The early clinical picture is similar to that of viral croup. However, instead of gradual improvement, patients develop higher fever, toxicity, and progressive or intermittent severe upper airway obstruction that is unresponsive to standard croup therapy. The incidence of sudden respiratory arrest or progressive respiratory failure is high; in such instances, airway intervention is required. Findings of toxic shock and the acute respiratory distress syndrome may also be seen. Recently, subsets of patients with tracheal membranes have been reported with a less severe clinical presentation. Aggressive medical treatment and debridement still must occur in these patients. A higher index of suspicion is required for this life-threatening condition.

B. Laboratory Findings and Imaging

The white cell count is usually elevated, with left shift. Cultures of tracheal secretions usually demonstrate one of the causative organisms. Lateral neck radiographs show a normal epiglottis but often severe subglottic and tracheal narrowing. Irregularity of the contour of the proximal tracheal mucosa can frequently be seen radiographically and should elicit concern. Bronchoscopy showing a normal epiglottis and the presence of copious purulent tracheal secretions and membranes confirm the diagnosis.

Treatment

Suspected bacterial tracheitis should be managed in a fashion similar to that for epiglottitis, with visualization of the airway in a controlled environment but with the added capability to debride the airway. The incidence of respiratory arrest or progressive respiratory failure is high, necessitating intubation. Patients often have thick, purulent tracheal secretions requiring debridement, and humidification, frequent suctioning, and intensive care monitoring are required to prevent endotracheal tube obstruction. Intravenous antibiotics to cover *S aureus, H influenzae*, and the other organisms are indicated. Thick secretions persist for several days, usually resulting in longer periods of intubation for bacterial tracheitis than for epiglottitis or croup. Despite the severity of this illness, the reported mortality rate is very low if it is recognized and treated promptly.

SUBGLOTTIC STENOSIS

Subglottic stenosis may be congenital, or more commonly may result from endotracheal intubation. Neonates and infants are particularly vulnerable to subglottic injury from intubation: The subglottis is the narrowest part of an infant’s airway, and the cricoid cartilage, which supports the subglottis, is the only cartilage that completely encircles the airway. The clinical presentation may vary from totally asymptomatic to the typical picture of severe upper airway obstruction. Patients with signs of stridor who repeatedly fail extubation are likely to have subglottic stenosis. Subglottic stenosis should also be suspected in children with multiple, prolonged, or severe episodes of croup. Diagnosis is made by direct visualization of the subglottic space with bronchoscopy and maneuvers to size the airway. Tracheostomy is often required when airway compromise is severe. Surgical intervention is ultimately required to correct the stenosis. Depending on the type of stenosis, a cricoid split in which the cricoid cartilage is surgically opened (better for acquired than for congenital lesions) may be tried. Laryngotracheal reconstruction in which a cartilage graft from another source (eg, rib) is used to expand the airway has become the standard procedure for symptomatic subglottic stenosis in children.
LARYNGEAL PAPILLOMATOSIS

Papillomas of the larynx are benign, warty growths that are difficult to treat and are the most common laryngeal neoplasm in children. Human papillomaviruses 6, 11, and 16 have been implicated as causative agents. A substantial percentage of mothers of patients with laryngeal papillomas have a history of genital condylomas at the time of delivery, so the virus may be acquired during passage through an infected birth canal.

The age at onset is usually 2–4 years, but juvenile-onset recurrent respiratory papillomatosis is well documented. A younger age of onset may be a worse prognostic indicator. Patients usually develop hoarseness, voice changes, croupy cough, or stridor that can lead to life-threatening airway obstruction. Diagnosis is by direct laryngoscopy. The larynx was involved at the time of diagnosis in over 95% of patients, most of whom had only one site involved.

Treatment is directed toward relieving airway obstruction, usually by surgical removal of the lesions. Tracheostomy is necessary when life-threatening obstruction or respiratory arrest occurs. Various surgical procedures (laser, cup forceps, or cryosurgery) have been used to remove papillomas, but recurrences are the rule, and frequent reoperation may be needed. The lesions occasionally spread down the trachea and bronchi, making surgical removal more difficult. The use of interferon therapy remains controversial. Fortunately, spontaneous remissions do occur, usually by puberty, so that the goal of therapy is to maintain an adequate airway until remission occurs.

CONGENITAL DISORDERS OF THE INTRATHORACIC AIRWAYS

MALACIA OF AIRWAYS

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Chronic monophonic wheeze with or without a barking cough.
- Respiratory symptoms do not respond to bronchodilators.

**General Considerations**

Tracheomalacia or bronchomalacia exists when the cartilaginous framework of the airway is inadequate to maintain airway patency. Because cartilage of the infant airway is normally soft, all infants may have some degree of dynamic collapse of a central airway when pressure outside the airway exceeds intraluminal pressure. In tracheomalacia, whether congenital or acquired, dynamic collapse leads to airway obstruction. The congenital variety may be isolated or associated with another developmental defect. Congenital tracheomalacia and bronchomalacia may also be associated with developmental abnormalities such as tracheoesophageal fistula, vascular ring, or cardiac anomalies causing extrinsic airway compression during development. Tracheomalacia is also associated with various syndromes. Congenital tracheomalacia may be localized to part of the trachea, or more commonly may involve the entire trachea as well as the remainder of the conducting airways. In severe cases, cartilage in the involved area may be missing or underdeveloped. Acquired tracheomalacia has been associated with long-term ventilation of premature newborns that results in chronic tracheal injury, severe tracheobronchitis, and airway compression due to tumors, abscess or infection, and cysts.

**Clinical Findings**

Coarse wheezing, cough, stridor, recurrent illnesses, recurrent wheezing that does not respond to bronchodilators, or radiographic changes are common findings. Symptoms classically present insidiously over the first few months of life and can increase with agitation, excitement, or upper respiratory tract infections. Diagnosis can be made by airway fluoroscopy or bronchoscopy. Barium swallow may be indicated to rule out coexisting conditions.

**Treatment**

Conservative treatment is usually indicated for the isolated condition, which generally improves over time with growth. Coexisting lesions such as tracheoesophageal fistulas and vascular rings need primary repair. In severe cases of tracheomalacia, intubation or tracheostomy may be necessary. However, this alone is seldom satisfactory because airway collapse continues to exist below the tip of the artificial airway. Positive pressure ventilation may be required to stent the collapsing airway. Surgical approaches to the problem (tracheopexy or aortopexy) may be considered as alternatives prior to or in an effort to wean off of ventilatory support.

**RESPIRATORY TRACT & MEDIASTINUM**

CHAPTER 18

VASCULAR RINGS & SLINGS

The most common vascular anomaly to compress the trachea or esophagus is a vascular ring. A vascular ring can be formed by a double aortic arch, a right aortic arch with left ligamentum arteriosum, or a patent ductus arteriosus. The pulmonary sling is created when the left pulmonary artery branches off from the right pulmonary artery. Other common vascular anomalies include an anomalous innominate, a left carotid artery, and an aberrant right subclavian artery. All but the right subclavian artery can cause tracheal compression and present in infancy with symptoms of chronic airway obstruction (stridor, coarse wheezing, and croupy cough). Symptoms are often worse in the supine position. Respiratory compromise is most severe with double aortic arch and may lead to apnea, respiratory arrest, or even death. Esophageal compression, present in all but anomalous innominate or carotid artery, may result in feeding difficulties, including dysphagia and vomiting. Barium swallow showing esophageal compression is the mainstay of diagnosis. Chest radiographs and echocardiograms may miss abnormalities. Anatomy can be further defined by angiography, chest CT with contrast, MRI or magnetic resonance angiography, or bronchoscopy.

Patients with significant symptoms require surgical correction, especially those with double aortic arch. Patients usually improve following correction but may have persistent but milder symptoms of airway obstruction due to associated tracheomalacia.

BRONCHOGENIC CYSTS

Bronchogenic cysts generally occur in the middle mediastinum (see later section on Mediastinal Masses) near the carina and adjacent to the major bronchi but can be found elsewhere in the lung. They range in size from 2–10 cm. Cyst walls are thin and may contain pus, mucus, or blood. Cysts develop from abnormal lung budding of the primitive foregut. They can be seen in involvement with other congenital pulmonary malformations such as pulmonary sequestration or lobar emphysema.

Clinically, respiratory distress can appear acutely in early childhood due to airway compression or infection of the bronchogenic cyst or they may remain asymptomatic into adulthood. Symptoms may include chronic wheezing, chronic cough, tachypnea, recurrent pneumonia, or stridor, depending on the location and size of the cysts and the degree of airway compression. However, all asymptomatic cysts will eventually become symptomatic with chest pain being the most common presenting complaint. On examination, the trachea may deviate from the midline, breath sounds over such areas will be decreased, and percussion over involved lobes may be hyperresonant due to air trapping.

The choice of diagnostic studies for bronchogenic cysts is controversial. Chest radiographs can show air trapping and hyperinflation of the affected lobes or may show a spherical lesion with or without an air-fluid level. However, early detected or smaller lesions may not be seen on chest radiographs. CT scan is the preferred imaging study and can differentiate solid versus cystic mediastinal masses and define the cyst’s relationship to the airways and the rest of the lung. A barium swallow can help determine whether the lesion communicates with the gastrointestinal tract. MRI and ultrasound are other imaging modalities used.

Treatment is surgical resection. Postoperatively, vigorous pulmonary physiotherapy is required to prevent complications (atelectasis or infection of the lung distal to the site of resection of the cyst).

FOREIGN BODY ASPIRATION

Aspiration of a foreign body into the respiratory tract is rarely observed. Onset is generally abrupt, with a history of the child running with food in the mouth or playing with seeds, small coins, or toys. Symptoms at the time of the ingestion are often abrupt and include cough, choking, or wheezing.

The foreign body can lodge itself anywhere along the respiratory tract. Often it is trapped in the supraglottic airway, triggering protective reflexes that result in laryngospasm. Small objects such as coins may pass through the glottis and obstruct the trachea. Finally, foreign bodies that lodge in the esophagus may compress the airway and cause dysphagia and respiratory distress.

The most commonly seen objects in foreign body aspiration include peanuts, hot dogs, popcorn, small coins, hard candy, and small toys. Children aged 6 months to 4 years are at highest risk, and many deaths are caused by foreign body aspiration and airway obstruction each year.

1. Foreign Bodies in the Upper Respiratory Tract

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Sudden onset of coughing or respiratory distress.
- Difficulty vocalizing.
Clinical Findings

The diagnosis is established by acute onset of choking along with inability to vocalize or cough and cyanosis with marked distress (complete obstruction), or with drooling, stridor, and ability to vocalize (partial obstruction).

Foreign bodies that lodge in the esophagus may compress the airway and cause respiratory distress. More typically, the foreign body lodges in the supraglottic airway, triggering protective reflexes that result in laryngospasm. Onset is generally abrupt, with a history of the child running with food in the mouth or playing with seeds, small coins, toys, and the like. Homes and child care centers in which an older sibling or child feeds age-inappropriate foods (eg, peanuts, hard candy, or carrot slices) to the younger child are typical. Without treatment, progressive cyanosis, loss of consciousness, seizures, bradycardia, and cardiopulmonary arrest can follow.

Treatment

The emergency treatment of upper airway obstruction due to foreign body aspiration is somewhat controversial. If complete obstruction is present, then one must intervene immediately. If partial obstruction is present, then the choking subject should be allowed to use his or her own cough reflex to remove the foreign body. If after a brief observation the obstruction increases or the airway becomes completely obstructed, acute intervention is required. The American Academy of Pediatrics and the American Heart Association distinguish between children younger than and older than age 1 year. A choking infant younger than age 1 year should be placed face down over the rescuer’s arm, with the head positioned below the trunk. Five measured back blows are delivered rapidly between the infant’s scapulas with the heel of the rescuer’s hand. If obstruction persists, the infant should be rolled over and five rapid chest compressions performed (similar to cardiopulmonary resuscitation). This sequence is repeated until the obstruction is relieved. In a choking child older than age 1 year, abdominal thrusts (Heimlich maneuver) may be performed, with special care in younger children because of concern about possible intra-abdominal organ injury.

Blind finger sweeps should not be performed in infants or children because the finger may actually push the foreign body further into the airway causing further obstruction. The airway may be opened by jaw thrust, and if the foreign body can be directly visualized, careful removal with the fingers or instruments (Magill forceps) can be attempted. Patients with persistent apnea and inability to achieve adequate ventilation may require emergency intubation, tracheotomy, or needle cricothyotomy, depending on the setting and the rescuer’s skills.

2. Foreign Bodies in the Lower Respiratory Tract

Clinical Findings

A. Symptoms and Signs

Respiratory symptoms and signs vary depending on the site of obstruction and the duration following the acute episode. For example, a large or central airway obstruction may cause marked distress. The acute cough or wheezing caused by a foreign body in the lower respiratory tract may diminish over time only to recur later as chronic cough or persistent wheezing, monophonic wheezing, asymmetrical breath sounds on chest examination, or recurrent pneumonia in one location. Foreign body aspiration should be suspected in children with chronic cough, persistent wheezing, or recurrent pneumonia. Long-standing foreign bodies may lead to bronchiectasis or lung abscess. Hearing asymmetrical breath sounds or localized wheezing also suggests a foreign body.

B. Imaging

Inspiratory and forced expiratory (obtained by manually compressing the abdomen during expiration) chest radiographs should be obtained if foreign body aspiration is suspected. Chest radiographs may be normal up to 25% of the time. If abnormal, the initial inspiratory view may show localized hyperinflation due to the ball-valve effect of the foreign body, causing distal air trapping or aeration within an area of atelectasis. A positive forced expiratory study shows a mediastinal shift away from the affected side. If airway obstruction is complete, atelectasis and related volume loss will be the major radiologic findings. Lateral decubitus views may be helpful if the child is too young to cooperate. Chest fluoroscopy is an alternative approach for detecting air trapping and mediastinal shift.

Treatment

When a foreign body is highly suspected, a normal chest radiograph should not rule out the possibility of an airway foreign body. If clinical suspicion persists based on two of three findings—history of possible aspiration, focal abnormal lung examination, or an abnormal chest radiograph—
then a bronchoscopy is indicated. Rigid bronchoscopy under general anesthesia is recommended. Flexible bronchoscopy may be helpful for follow-up evaluations (after the foreign object has been removed).

Children with suspected acute foreign body aspiration should be admitted to the hospital for evaluation and treatment. Chest postural drainage is no longer recommended because the foreign body may become dislodged and obstruct a major central airway. Bronchoscopy should not be delayed in children with respiratory distress but should be performed as soon as the diagnosis is made—even in children with more chronic symptoms. Following the removal of the foreign body, β-adrenergic nebulization treatments followed by chest physiotherapy are recommended to help clear related mucus or treat bronchospasm. Failure to identify a foreign body in the lower respiratory tract can result in bronchiectasis or lung abscess. This risk justifies an aggressive approach to suspected foreign bodies in suspicious cases.

**BRONCHIOLITIS**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- **Clinical syndrome characterized by one or more of the following findings:** coughing, tachypnea, labored breathing, and hypoxia.
- **Irritability, poor feeding, vomiting.**
- **Wheezing and crackles on chest auscultation.**

Bronchiolitis is the most common serious acute respiratory illness in infants and young children. One to 3% of infants with bronchiolitis will require hospitalization, especially during the winter months. The typical presentation is acute onset of tachypnea, cough, and expiratory wheezing after 1–2 days of rhinorrhea. RSV is by far the most common viral cause of acute bronchiolitis. Parainfluenza, human metapneumovirus, influenza, adenovirus, *Mycoplasma*, *Chlamydia*, *Ureaplasma*, and *Pneumocystis* are less common causes of bronchiolitis during early infancy. Major concerns include not only the acute effects of bronchiolitis but also the possible development of chronic airway hyperreactivity (asthma). Bronchiolitis due to RSV infection contributes substantially to morbidity and mortality in children with underlying medical disorders, including chronic lung disease of prematurity, CF, congenital heart disease, and immunodeficiency.

### Clinical Findings

#### A. Symptoms and Signs

The usual course of RSV bronchiolitis is 1–2 days of fever, rhinorrhea, and cough, followed by wheezing, tachypnea, and respiratory distress. Typically the breathing pattern is shallow, with rapid respirations. Nasal flaring, cyanosis, retractions, and rales may be present, along with prolongation of the expiratory phase and wheezing, depending on the severity of illness. Some young infants present with apnea and few findings on auscultation but may subsequently develop rales, rhonchi, and expiratory wheezing.

#### B. Laboratory Findings and Imaging

A viral nasal wash may be performed to identify the causative pathogen but is not necessary to make the diagnosis of bronchiolitis. The peripheral white blood cell count may be normal or may show a mild lymphocytosis. Chest radiographic findings are generally nonspecific and typically include hyperinflation, peribronchial cuffing, increased interstitial markings, and subsegmental atelectasis.

### Prevention & Treatment

The most effective prevention against RSV infection is to use proper handwashing techniques and to reduce exposure to potential environmental risk factors. Major challenges have impeded the development of an RSV vaccine, but a licensed product may be expected in the near future. Prophylaxis with a monoclonal antibody (palivizumab) has proven effective in reducing the rate of hospitalization and associated morbidities in high-risk premature infants and those with chronic cardiopulmonary conditions.

Although most children with RSV bronchiolitis are readily treated as outpatients, hospitalization is required in infected children with hypoxemia on room air, a history of apnea, moderate tachypnea with feeding difficulties, and marked respiratory distress with retractions. Children at high risk for hospitalization include young infants (under 6 months of age), especially with any history of prematurity, and those with underlying chronic cardiopulmonary disorders. While in the hospital, treatment should include supportive strategies such as frequent suctioning and providing adequate fluids to maintain hydration. If hypoxemia is present, supplemental oxygen should be administered. Although bronchodilators and corticosteroids may attenuate airway obstruction, their use remains controversial and empiric, and patients should be assessed individually to determine responsiveness.

In immunocompromised patients, especially bone marrow transplant recipients, a combination of RSV intravenous immune globulin and the antiviral ribavirin has been tried.
Therapy for RSV, however, remains limited, controversial, and mostly supportive.

**Prognosis**

The prognosis for the majority of infants with acute bronchiolitis is very good. With improved supportive care and prophylaxis with palivizumab, the mortality rate among high-risk infants has decreased substantially.

**DISORDERS OF MUCOCILIARY CLEARANCE**

Mucociliary clearance is the primary defense mechanism for the lung. Inhaled particles including microbial pathogens are entrapped in mucus on the airway surface, then cleared by the coordinated action of cilia. The volume and composition of airway surface liquid influence the efficiency of ciliary function and mucus clearance. The two main genetic diseases of mucociliary clearance involve disorders of ion transport (cystic fibrosis, CF) and disorders in ciliary function (primary ciliary dyskinesia, PCD).

**CYSTIC FIBROSIS**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Greasy, bulky, malodorous stools; failure to thrive.
- Recurrent respiratory infections.
- Digital clubbing on examination.
- Bronchiectasis on chest imaging.
- Sweat chloride > 60 mmol/L.

**General Considerations**

CF, an autosomal recessive disease, results in a syndrome of chronic sinopulmonary infections, malabsorption, and nutritional abnormalities. It is one of the most common lethal genetic diseases in the United States, with an incidence of approximately 1:3000 among Caucasians. Although CF is characterized by abnormalities in the hepatic, gastrointestinal, and male reproductive systems, lung disease is the major cause of morbidity and mortality. Most individuals with CF develop obstructive lung disease associated with chronic infection that leads to progressive loss of pulmonary function.

The cause of CF is a defect in a single gene on chromosome 7 that encodes a cyclic adenosine monophosphate–regulated chloride channel called the cystic fibrosis transmembrane conductance regulator (CFTR) protein. CFTR functions primarily as an ion channel and controls the movement of salt and water into and out of epithelial cells lining the airways, biliary tree, intestines, vas deferens, sweat ducts, and pancreatic ducts. Approximately 1500 disease-causing mutations in the CF gene have been identified. The most common mutation, ΔF508, is a deletion of three base pairs. This and other gene mutations lead to defects or deficiencies in CFTR, causing problems in salt and water movement across cell membranes, resulting in abnormally thick secretions in various organ systems and critically altering host defense in the lung.

**Clinical Findings**

**A. Symptoms and Signs**

Approximately 15% of newborns with CF present at birth with meconium ileus, a severe intestinal obstruction resulting from inspissation of tenacious meconium in the terminal ileum. Meconium ileus is virtually diagnostic of CF, so the infant should be treated presumptively as having CF until a sweat test or genotyping can be obtained.

During infancy and beyond, a common presentation of CF is failure to thrive. These children fail to gain weight despite good appetite and typically have frequent, bulky, foul-smelling, oily stools. These symptoms are the result of severe exocrine pancreatic insufficiency, the failure of the pancreas to produce sufficient digestive enzymes to allow breakdown and absorption of fats and protein. Pancreatic insufficiency occurs in over 85% of persons with CF. (Chapter 21 describes gastrointestinal and hepatobiliary manifestations of CF; see also Table 21–9 there.) Infants with undiagnosed CF may also present with hypoproteinemia with or without edema, anemia, and deficiency of the fat-soluble vitamins A, D, E, and K, because of ongoing steatorrhea.

From a respiratory standpoint, clinical manifestations include productive cough, wheezing, chronic bronchitis and recurrent pneumonias, progressive obstructive airways disease, exercise intolerance, dyspnea, hemoptysis, anorexia, and weight loss. CF lung disease is characterized by a cycle of chronic, persistent infections with CF-related pathogens and an excessive inflammatory response that progressively damages the airways and lung parenchyma. This results in a characteristic airflow obstruction on lung function testing and bronchiectasis and other structural lung abnormalities on chest imaging (best demonstrated by high-resolution CT scans). Airway infection with bacteria, including *S. aureus* and *H. influenzae*, often begins in the first few months of life,
even in asymptomatic infants. Eventually, *Pseudomonas aeruginosa* becomes the predominant pathogen. Acquisition of the characteristic mucoid *Pseudomonas* is associated with a more rapid decline in pulmonary function.

An acute change in respiratory signs and symptoms from the subject’s baseline is generically termed a pulmonary exacerbation. Clinically, an exacerbation is typically manifested by increased cough and sputum production, decreased exercise tolerance, malaise, and anorexia. These symptoms are usually associated with decreased measures of lung function, new chest radiographic findings, or both. Treatment for pulmonary exacerbations generally consists of antibiotics and augmented airway clearance.

CF should also be considered in infants and children who present with severe dehydration and hypochloremic alkalosis. Other findings that should prompt a diagnostic evaluation for CF include unexplained bronchiectasis, rectal prolapse, nasal polyps, chronic sinusitis, and unexplained pancreatitis or cirrhosis.

B. Diagnostic Studies

The diagnosis of CF is made by a sweat chloride concentration greater than 60 mmol/L, in the presence of one or more typical clinical features (chronic sinopulmonary disease, pancreatic insufficiency, salt loss syndromes) or an appropriate family history (sibling or first cousin who has CF). The most acceptable type of sweat test is performed by iontophoresis of pilocarpine into the skin to stimulate sweating. Sweat then is collected and analyzed for chloride. This test should be performed at a CF Foundation–accredited laboratory. A diagnosis can also be confirmed by genotyping that reveals two alleles that have CF-causing mutations. Many states now perform newborn screening for CF by measuring immunoreactive trypsin (IRT), a pancreatic enzyme, in blood. Most infants with CF have elevated IRT in the newborn period. In newborns with elevated IRT, the diagnosis of CF must then be confirmed by sweat testing, mutation analysis, or both.

**Treatment**

It is strongly recommended that individuals with CF be followed at a CF Foundation–accredited CF care center (http://www.cff.org).

The cornerstone of gastrointestinal treatment is pancreatic enzyme supplementation. Persons with CF are required to take pancreatic enzyme capsules immediately prior to each meal and with snacks. Occasionally, enzyme supplementation alone does not control the malabsorption, and antacids are added to the regimen. Individuals should also take daily multivitamins that contain vitamins A, D, E, and K. Moreover, caloric supplements are often added to the patient’s diet to optimize growth.

Airway clearance therapy and aggressive antibiotic use form the mainstays of treatment for CF lung disease. Antibiotic therapy appears to be one of the primary reasons for the increased life expectancy of persons with CF. Three evidence-based medications that are now routinely used in many persons with CF are an inhaled mucolytic agent, recombinant human DNase (Pulmozyme), inhaled tobramycin (TOBI), and oral azithromycin for those with chronic *Pseudomonas* infection. These therapies have been shown to maintain lung function and reduce the need for hospitalizations and intravenous antibiotics. Bronchodilators and anti-inflammatory therapies are also frequently used.

**Prognosis**

A few decades ago, CF was fatal in early childhood. Now the median life expectancy is around 35 years of age. The rate of lung disease progression usually determines survival. Lung transplantation may be performed in those with end-stage lung disease. In addition, new treatments, including gene therapy trials and agents that modulate CFTR protein function, are being developed based on improved understanding of the disease at the cellular and molecular levels.

**Primary Ciliary Dyskinesia**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Chronic bronchitis, sinusitis, and otitis.
- Situs inversus in approximately 50% of cases.
- Unexplained respiratory distress in the newborn period.
- Consistent ultrastructural defect of cilia demonstrated by electron microscopy.

**General Considerations**

PCD, also known as immotile cilia syndrome or Kartagener syndrome, is a human genetic disease associated with abnormal ciliary structure and function. Occurring in approximately 1 in 15,000 births, PCD is an inherited disease that causes impaired clearance of bacteria from the lung, paranasal sinuses, and middle ear. Half of the patients with PCD have their internal organs reversed (situs abnormalities), and men are usually infertile.

**Clinical Findings**

**A. Symptoms and Signs**

Children with PCD have a variety of clinical features including chronic productive cough, wheezing, nasal congestion
and rhinorrhea, chronic sinusitis, bronchitis, and pneumonias. Recurrent, chronic otitis media is a serious problem, and hearing loss is common. A history of transient neonatal respiratory distress and unexplained atelectasis in the newborn period is frequently elicited. Approximately 50% of PCD patients have situs inversus totalis or other organ rotation abnormalities, suggesting a role for embryonic cilia in the rotation of internal organs. The diagnosis of PCD should also be considered in any patients with unexplained bronchiectasis or in males with infertility issues.

B. Diagnostic Studies

The diagnosis of PCD currently requires a compatible clinical phenotype and specific ultrastructural defects of the cilia detected by transmission electron microscopy. Cilia samples may be obtained from either the upper airways (nasal passage) or lower airways (trachea). Semen collection from older male patients can also be obtained to analyze sperm tails, which have the same ultrastructure as cilia. Significant expertise is required to produce high-quality transmission electron micrographs of cilia, and to distinguish primary (genetic) defects from secondary (acquired) defects in ciliary ultrastructure. Functional assessments of cilia consist of crude measures of nasal mucociliary clearance (the saccharin test), or measures of lung mucociliary clearance, using radiographic techniques. The current limitations in diagnosis of PCD provide a compelling case to define disease-causing genetic mutations, which will allow great improvement in the identification and diagnosis of PCD through genetic testing. Although structural and functional assessments of cilia have been the diagnostic gold standard in PCD diagnosis, nasal nitric oxide has the potential to become a useful adjunctive diagnostic test for PCD. Recent studies have demonstrated extremely low levels of nasal nitric oxide in persons with PCD, suggesting that nasal nitric oxide could be used as a screening test for PCD.

Treatment

At present, no specific therapies are available to correct the ciliary dysfunction in PCD. Management includes aggressive airway clearance therapy and frequent courses of antibiotics to treat bacterial infections in the airways, sinuses, and middle ear. No randomized clinical trials have been conducted in this disease because it is so rare and most centers follow only a few PCD patients. A national consortium has been created to improve diagnostic techniques for PCD, including genetic testing to better define the pathogenesis of PCD and study treatments in this population (http://rarediseasesnetwork.epi.usf.edu/).

Prognosis

The progression of lung disease in PCD is quite variable and for most affected individuals is less severe than in CF. Importantly, though, persons with PCD are at risk for chronic lung disease with bronchiectasis. With monitoring and aggressive treatment during times of illness, most individuals with PCD should experience a normal or near-normal life span.

B.RONCHIECTASIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Chronic cough with sputum production.
- Rhonchi or wheezes (or both) on chest auscultation.
- Diagnosis is confirmed by high-resolution CT scan.

General Considerations

Bronchiectasis is the permanent dilation of bronchi. The dilation may be regular, with the airway continuing to have a smooth outline (cylindrical bronchiectasis); irregular, with areas of dilation and constriction (varicose bronchiectasis); or marked, with destruction of structural components of the airway wall (saccular or cystic bronchiectasis).

Bronchiectasis results from airway obstruction by retained mucus secretions or inflammation in response to chronic or repeated infection. It occurs either as a consequence of a preceding illness (severe pneumonia or foreign body aspiration) or as a manifestation of an underlying systemic disorder (CF, PCD, or immunodeficiency).

Clinical Findings

A. Symptoms and Signs

Persons with bronchiectasis will typically have chronic cough, purulent sputum, fever, and weight loss. Recurrent respiratory infections and dyspnea on exertion are also common. Hemoptysis occurs less frequently in children than in adults with bronchiectasis. On physical examination, finger clubbing may be seen. Rales, rhonchi, and decreased air entry are often noted over the bronchiectatic areas.

B. Laboratory Findings and Imaging

Cultures from the lower respiratory tract usually reveal normal oropharyngeal flora. These include Streptococcus pneumoniae, Staphylococcus aureus, and nontypeable H influenzae. Pseudomonas aeruginosa can also be found in children with bronchiectasis, even in those without CF.

Chest radiographs may be mildly abnormal with slightly increased bronchovascular markings or areas of atelectasis, or
they may demonstrate cystic changes in one or more areas of the lung. The extent of bronchiectasis is best defined by high-resolution CT scan of the lung, which often reveals far wider involvement of lung than expected from the plain chest radiograph. Pulmonary function testing often reveals airflow obstruction. Evaluation of lung function after use of a bronchodilator is helpful in assessing the benefit a patient may have from bronchodilators. Serial assessments of lung function help define the progression or resolution of the disease.

**Differential Diagnosis**

Bronchiectasis has numerous causes. It can occur following severe respiratory tract infections by bacteria (*Bordetella pertussis*), viruses (adenovirus), or other organisms (*Mycobacterium tuberculosis*). Bronchiectasis is commonly seen in persons with CF, PCD, immunodeficiency, and collagen-vascular conditions. Other diagnostic considerations include foreign body aspiration, chronic aspiration of gastric or oropharyngeal contents, and allergic bronchopulmonary aspergillosis.

**Treatment**

Aggressive antibiotic therapy during pulmonary exacerbations and routine airway clearance are mainstays of treatment. Inhaled mucolytic agents and bronchodilators may also be of benefit in individual patients.

Surgical removal of an area of lung affected with severe bronchiectasis is considered when the response to medical therapy is poor. Other indications for operation include severe localized disease, repeated hemoptysis, and recurrent pneumonia in one area of lung. If bronchiectasis is widespread, surgical resection offers little advantage.

**Prognosis**

The prognosis depends on the underlying cause and severity of bronchiectasis, the extent of lung involvement, and the response to medical management. Good pulmonary hygiene and avoidance of infectious complications in the involved areas of lung may reverse cylindric bronchiectasis.

---

**BRONCHIOLITIS OBLITERANS**

Bronchiolitis obliterans is characterized by partial or complete occlusion of the lumens of terminal and respiratory bronchioles by inflammatory and fibrous tissue. This condition follows damage to the lower respiratory tract from any of a number of insults, such as inhalation of toxic gases, infections (adenovirus, influenza virus, rubeola virus, *Bordetella*, or *Mycoplasma*), connective tissue diseases, transplantation, and aspiration. Bronchiolitis obliterans may also develop in children who have Stevens-Johnson syndrome with pulmonary involvement. Many cases of bronchiolitis obliterans are idiopathic. Adenovirus-induced bronchiolitis obliterans occurs more frequently in the Native American population.

**Clinical Findings**

**A. Symptoms and Signs**

Persons with bronchiolitis obliterans usually experience dyspnea, coughing, and exercise intolerance. This diagnosis should be considered in children with persistent cough, wheezing, crackles, or hypoxemia following an episode of acute pneumonia or bronchiolitis.

**B. Laboratory Findings and Imaging**

Chest radiograph abnormalities include evidence of localized or generalized air trapping as well as (in some cases) nodular densities and alveolar opacification. Scattered areas of matched decreases in ventilation and perfusion are seen when the lung is scanned. Pulmonary angiograms reveal decreased vasculature in involved lung, and bronchograms show marked pruning of the bronchial tree. An assessment of lung function demonstrates an obstructive process that may be combined with evidence of restriction. Inhaled bronchodilators or corticosteroids provide little improvement in lung function.

**Differential Diagnosis**

Poorly treated asthma, CF, and bronchopulmonary dysplasia must be considered in children with persistent airway obstruction. A trial of medications (including bronchodilators and corticosteroids) may help to determine the reversibility of the process when the primary differential is between asthma and bronchiolitis obliterans. Although the results of imaging and pulmonary function testing are very suggestive, the most definitive way to establish a diagnosis is by lung biopsy.

**Complications**

Sequelae of bronchiolitis obliterans include persistent airway obstruction, recurrent wheezing, bronchiectasis, chronic atelectasis, recurrent pneumonia, and unilateral hyperlucent lung syndrome.

**Treatment**

Supplemental oxygen should be given to patients with oxygen desaturation during normal activities or sleep. In addition, early treatment should be directed at preventing ongoing airway damage due to problems such as aspiration, which may be either the primary insult or an acquired problem secondary to marked hyperinflation. The effective-
ness of other forms of treatment may be more difficult to evaluate. Oral and inhaled bronchodilators may reverse airway obstruction if the disease has a reactive component. Many children also receive at least one course of corticosteroid treatment in an attempt to reverse the obstruction or prevent ongoing damage. Antibiotics should be used as indicated for pneumonia.

**Prognosis**

Prognosis may depend in part on the underlying cause as well as the age at which the insult occurred. The course varies from mild asthma-like symptoms to rapidly fatal deterioration despite therapy.

**BRONCHOPULMONARY DYSPLASIA**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Acute respiratory distress in the first week of life.
- Required oxygen therapy or mechanical ventilation, with persistent oxygen requirement at 36 weeks' gestational age.
- Persistent respiratory abnormalities, including physical signs and radiographic findings.

**General Considerations**

Bronchopulmonary dysplasia (BPD) remains one of the most significant sequelae of acute respiratory distress in the neonatal intensive care unit, with an incidence of about 30% for infants with a birth weight of less than 1000 g. This disease was first characterized in 1967 when Northway and coworkers reported the clinical, radiologic, and pathologic findings in a group of premature newborns that required prolonged mechanical ventilation and oxygen therapy to treat hyaline membrane disease. The progression from acute hyaline membrane disease to chronic lung disease was divided into four stages: acute respiratory distress shortly after birth, usually hyaline membrane disease (stage I); clinical and radiographic worsening of the acute lung disease, often due to increased pulmonary blood flow secondary to a patent ductus arteriosus (stage II); and progressive signs of chronic lung disease (stages III and IV).

The pathologic findings and clinical course of BPD in recent years have changed due to a combination of new therapies (surfactants, prenatal glucocorticoids, and different ventilation strategies) and increased survival of infants born at earlier gestational ages. Although the incidence of BPD has not changed, the severity of the lung disease has decreased. Pathologically this “new” BPD is characterized by a reduction in inflammation, decreased alveolar number, and a dysmorphic vascular structure.

**Pathogenesis**

The precise mechanism that results in the development of BPD is unclear. The premature lung makes insufficient functional surfactant; furthermore, the antioxidant defense mechanisms are not sufficiently mature to protect the lung from the toxic oxygen metabolites, and lungs destined to develop BPD show early inflammation and hypercellularity followed by healing with fibrosis. Thus abnormal lung mechanics due to structural immaturity, surfactant deficiency, atelectasis, and pulmonary edema—plus lung injury secondary to hypoxia and mechanical ventilation—lead to further abnormalities of lung function, causing increases in ventilator and oxygen requirements and resulting in a vicious cycle that compounds the progression of lung injury. Excessive fluid administration, patent ductus arteriosus, pulmonary interstitial emphysema, pneumothorax, infection, pulmonary hypertension, and inflammatory stimuli secondary to lung injury or infection also play important roles in the pathogenesis of the disease. Although the exact mechanisms are not completely understood, BPD represents the consequences of lung injury caused by oxygen toxicity, barotrauma, and inflammation superimposed on a susceptible, generally immature lung.

**Clinical Findings**

A recent summary of a National Institutes of Health workshop on BPD proposes a definition of the disease that includes oxygen requirement for more than 28 days, a history of positive pressure ventilation or continuous positive airway pressure, and gestational age. The new definition accommodates several key observations regarding the disease, as follows: (1) although most of these children were premature and had hyaline membrane disease, full-term newborns with such disorders as meconium aspiration or persistent pulmonary hypertension can also develop bronchopulmonary dysplasia; (2) some extremely preterm newborns require minimal ventilator support yet subsequently develop a prolonged oxygen requirement despite the absence of severe acute manifestations of respiratory failure; (3) newborns dying within the first weeks of life can already have the aggressive, fibroproliferative pathologic lesions that resemble broncho-pulmonary dysplasia; and (4) physiologic abnormalities (increased airway resistance) and biochemical markers of lung injury (altered protease-antiprotease ratios, and increased inflammatory cells and mediators), which may be predictive of BPD, are already present in the first week of life.

**Differential Diagnosis**

The radiologic appearance of BPD is changing, and severe chronic lung findings of fibrosis with infiltrate are less common. The changes in severe BPD necessitate ruling out...
meconium aspiration syndrome, congenital infection (eg, with cytomegalovirus or *Ureaplasma*), cystic adenomatoid malformation, recurrent aspiration, pulmonary lymphangiectasia, total anomalous pulmonary venous return, overhydration, and idiopathic pulmonary fibrosis.

**Treatment**

**A. Clinical Course**

The clinical course of infants with BPD ranges from a mild increased oxygen requirement that gradually resolves over a few months to more severe disease requiring chronic tracheostomy and mechanical ventilation for the first 2 years of life. In general, patients show slow, steady improvements in oxygen or ventilator requirements but can have frequent respiratory exacerbations leading to frequent and prolonged hospitalizations. Clinical management generally includes careful attention to growth, nutrition (caloric requirements of infants with oxygen dependence and respiratory distress are quite high), metabolic status, developmental and neurologic status, and related problems, along with the various cardiopulmonary abnormalities described in a later discussion.

**B. Corticosteroid Therapy**

Short courses of postnatal glucocorticoid therapy have been helpful in increasing the success of weaning from the ventilator. Longer courses of postnatal glucocorticoids have been linked to an increased incidence of cerebral palsy. Inhaled glucocorticoids may help reduce the need for systemic steroids, but the overall incidence of BPD has not been affected. Early use of surfactant therapy with adequate lung recruitment increases the chance for survival without BPD and can decrease the overall mortality and reduce the need for ventilation. Thus early interventions are important prior to the development of BPD to decrease morbidity and mortality. Inhaled corticosteroids together with occasional use of β-adrenergic agonists are commonly part of the treatment plan. Part of the rationale for the use of corticosteroids is to decrease lung inflammation and enhance responsiveness to β-adrenergic drugs, as in the treatment of severe asthma. β-Adrenergic agonists followed by chest physiotherapy are often used for the thick secretions that may contribute to airway obstruction or recurrent atelectasis.

**C. Airway Evaluation**

Children with significant stridor, sleep apnea, chronic wheezing, or excessive respiratory distress need diagnostic bronchoscopy to evaluate for structural lesions (eg, subglottic stenosis, vocal cord paralysis, tracheal stenosis, tracheomalacia, bronchial stenosis, and granulomatous bronchial polyps). In addition, the contribution of gastroesophageal reflux and aspiration should be considered in the face of worsening chronic lung disease.

**D. Diuretic Therapy**

Salt and water retention secondary to chronic hypoxemia, hypercapnia, or other stimuli may be present. Chronic or intermittent diuretic therapy is commonly used if rales or signs of persistent pulmonary edema are present, and clinical studies show acute improvement in lung function with this therapy. Unfortunately, diuretics often have adverse effects, including severe volume contraction, hypokalemia, alkalosis, and hyponatremia. Potassium and arginine chloride supplements are commonly required.

**E. Management of Pulmonary Hypertension**

Infants with BPD are at risk of developing pulmonary hypertension, and in many of these children even mild hypoxemia can cause significant elevations of pulmonary arterial pressure. To minimize the harmful effects of hypoxemia, the arterial oxygen saturation should be kept above 93%, with care to avoid hyperoxia during retinal vascular development. Electrocardiographic and echocardiographic studies should be performed to monitor for the development of right ventricular hypertrophy. If hypertrophy persists or if it develops where it was not previously present, intermittent hypoxemia should be considered and further assessments of oxygenation pursued, especially while the infant sleeps. Infants with a history of intubation can develop obstructive sleep apnea secondary to a high-arched palate or subglottic narrowing. Barium swallow, esophageal pH probe studies, bronchoscopy, and cardiac catheterization will diagnose unsuspected cardiac or pulmonary lesions that contribute to the underlying pathophysiology, such as aspiration, tracheomalacia, obstructive sleep apnea, and anatomic cardiac lesions. Long-term care should include monitoring for systemic hypertension and the development of left ventricular hypertrophy.

**F. Nutrition**

Nutritional problems in infants may be due to increased oxygen consumption, feeding difficulties, gastroesophageal reflux, and chronic hypoxemia. Hypercaloric formulas and gastrostomies are often required to ensure adequate intake while avoiding overhydration. Influenza vaccination is recommended. With the onset of acute wheezing secondary to suspected viral infection, rapid diagnostic testing for RSV infection may facilitate early treatment. Immune prophylaxis of RSV reduces the morbidity of bronchiolitis in infants with BPD.

**G. Ventilation**

For children who remain ventilator-dependent, attempts should be made to maintain PaCO₂ below 60 mm Hg—even when pH is normal—because of the potential adverse effects of hypercapnia on salt and water retention, cardiac function, and perhaps pulmonary vascular tone. Changes in ventilator settings in children with severe lung disease should be slow,
because the effects of many of the changes may not be apparent for days.

**Prognosis**

Surfactant replacement therapy has had a significant effect on reducing morbidity and mortality from BPD. Infants of younger gestational age are surviving in greater numbers. Surprisingly, the effect of neonatal care has not decreased the incidence of BPD significantly, as 50% of survivors go on to develop this diagnosis. The disorder typically develops in the most immature infants, but the long-term outlook for most survivors is generally favorable. Long-term follow-up studies suggest that lung function may be altered for life. Hyperinflation and damage to small airways has been reported in children 10 years out from the first signs of BPD. In addition, these infants are at a higher risk for developing such sequelae as persistent airway hyperreactivity, exercise intolerance, pulmonary hypertension, increased risk for chronic obstructive pulmonary disease, and perhaps abnormal lung growth. As smaller, more immature infants survive, abnormal neurodevelopmental outcomes become more likely. The incidence of cerebral palsy, hearing loss, vision abnormalities, spastic diplegia, and developmental delays is increased. Feeding abnormalities, behavior difficulties, and increased irritability have all been reported. Finally, children with BPD frequently develop airway obstruction, hyperreactive airways, and decreased oxygen saturation during exercise. This should be taken into account for children residing at higher altitudes. A focus on good nutrition, prophylaxis against respiratory pathogens and airway hyperreactivity, and attention to school performance continue to provide the best outcomes. Patience, continued family support, attention to developmental issues, and speech and physical therapy help to improve the long-term outlook.

**CONGENITAL MALFORMATIONS OF THE LUNG**

What follows is a brief description of selected congenital pulmonary malformations.

**PULMONARY AGENESIS & HYPOPLASIA**

With unilateral pulmonary agenesis (complete absence of one lung), the trachea continues into a main bronchus and often has complete tracheal rings. The left lung is affected more often than the right. With compensatory postnatal growth, the remaining lung often herniates into the contralateral chest. Chest radiographs show a mediastinal shift toward the affected side, and vertebral abnormalities may be present. Absent or incomplete lung development may be associated with other congenital abnormalities, such as absence of one or both kidneys or fusion of ribs, and the outcome is primarily related to the severity of associated lesions. About 50% of patients survive; the mortality rate is higher with agenesis of the right lung than of the left lung. This difference is probably not related to the higher incidence of associated anomalies but rather to a greater shift in the mediastinum that leads to tracheal compression and distortion of vascular structures.

Pulmonary hypoplasia is incomplete development of one or both lungs, characterized by a reduction in alveolar number and a reduction in airway branches. Pulmonary hypoplasia is present in up to 10–15% of perinatal autopsies. The hypoplasia can be a result of an intrathoracic mass, resulting in lack of space for the lungs to grow; decreased size of the thorax; decreased fetal breathing movements; decreased blood flow to the lungs; or possibly a primary mesodermal defect affecting multiple organ systems. Congenital diaphragmatic hernia is the most common cause, with an incidence of 1:2200 births. Other causes include extralobar sequestration, diaphragmatic entration or hypoplasia, thoracic neurentoblastoma, fetal hydrops, and fetal hydrothorax. Chest cage abnormalities, diaphragmatic elevation, oligohydranmios, chromosomal abnormalities, severe musculoskeletal disorders, and cardiac lesions may also result in hypoplastic lungs. Postnatal factors may play important roles. For example, infants with advanced BPD can have pulmonary hypoplasia.
CHAPTER 18

Clinical Findings

A. Symptoms and Signs

The clinical presentation is highly variable and is related to the severity of hypoplasia as well as associated abnormalities. Lung hypoplasia is often associated with pneumothorax. Some newborns present with perinatal distress, severe acute respiratory distress, and persistent pulmonary hypertension of the newborn secondary to primary pulmonary hypoplasia (without associated anomalies). Children with lesser degrees of hypoplasia may present with chronic cough, tachypnea, wheezing, and recurrent pneumonia.

B. Laboratory Findings and Imaging

Chest radiographic findings include variable degrees of volume loss in a small hemithorax with mediastinal shift. Pulmonary agenesis should be suspected if tracheal deviation is evident on the chest radiograph. The chest CT scan is the optimal diagnostic imaging procedure if the chest radiograph is not definitive. Ventilation-perfusion scans, angiography, and bronchoscopy are often helpful in the evaluation, demonstrating decreased pulmonary vascularity or premature blunting of airways associated with the maldeveloped lung tissue. The degree of respiratory impairment is defined by analysis of arterial blood gases.

Treatment & Prognosis

Treatment is supportive. The outcome is determined by the severity of underlying medical problems, the extent of the hypoplasia, and the degree of pulmonary hypertension.

PULMONARY SEQUESTRATION

Pulmonary sequestration is nonfunctional pulmonary tissue that does not communicate with the tracheobronchial tree and receives its blood supply from one or more anomalous systemic arteries. This abnormality originates during the embryonic period of lung development. It is classified as either extralobar or intralobar. Extralobar sequestration is a mass of pulmonary parenchyma anatomically separate from the normal lung, with a distinct pleural investment. Its blood supply derives from the systemic circulation (more typical), from pulmonary vessels, or from both. Rarely, it communicates with the esophagus or stomach. Pathologically, extralobar sequestration appears as a solitary thoracic lesion near the diaphragm. Abdominal sites are rare. Size varies from 0.5–12 cm. The left side is involved in over 90% of cases. In contrast to intralobar sequestrations, venous drainage is usually through the systemic or portal venous system.

Histologic findings include uniformly dilated bronchioles, alveolar ducts, and alveoli. Occasionally the bronchial structure appears normal; however, often the cartilage in the wall is deficient, or no cartilage-containing structures can be found. Lymphangieactasia is sometimes found within the lesion. Extralobar sequestration can be associated with other anomalies, including bronchogenic cysts, heart defects, and diaphragmatic hernia, the latter occurring in over half of cases.

Intralobar sequestration is an isolated segment of lung within the normal pleural investment that often receives blood from one or more arteries arising from the aorta or its branches. Intralobar sequestration is usually found within the lower lobes (98%), two thirds are found on the left side, and it is rarely associated with other congenital anomalies (< 2% versus 50% with extralobar sequestration). It rarely presents in the newborn period (unlike extralobar sequestration). Some researchers have hypothesized that intralobar sequestration is an acquired lesion secondary to chronic infection. Clinical presentation includes chronic cough, wheezing, or recurrent pneumonias. Rarely, patients with intralobar sequestration can present with hemoptysis. Diagnosis is often made by angiography, which shows large systemic arteries perfusing the lesion. Recently spiral CT scans with contrast or magnetic resonance angiography have proved useful in identifying anomalous systemic arterial supply to the lung. Treatment is usually by surgical resection.

CONGENITAL LOBAR EMPHYSEMA

Patients with congenital lobar emphysema—also known as infantile lobar emphysema, congenital localized emphysema, unilobar obstructive emphysema, congenital hypertrophic lobar emphysema, or congenital lobar overinflation—present most commonly with severe neonatal respiratory distress or...
progressive respiratory impairment during the first year of life. Rarely the mild or intermittent nature of the symptoms in older children or young adults results in delayed diagnosis. Most patients are white males. Although the cause of congenital lobar emphysema is not well understood, some lesions show bronchial cartilaginous dysplasia due to abnormal orientation or distribution of the bronchial cartilage. This leads to expiratory collapse, producing obstruction and the symptoms outlined in the following discussion.

Clinical Findings

A. Symptoms and Signs
Clinical features include respiratory distress, tachypnea, cyanosis, wheezing, retractions, and cough. Breath sounds are reduced on the affected side, perhaps with hyperresonance to percussion, mediastinal displacement, and bulging of the chest wall on the affected side.

B. Imaging
Radiologic findings include overdistention of the affected lobe (usually an upper or middle lobe; > 99%), with wide separation of bronchovascular markings, collapse of adjacent lung, shift of the mediastinum away from the affected side, and a depressed diaphragm on the affected side. The radiographic diagnosis may be confusing in the newborn because of retention of alveolar fluid in the affected lobe causing the appearance of a homogeneous density. Other diagnostic studies include chest radiograph with fluoroscopy, ventilation-perfusion study, and chest CT scan followed by bronchoscopy, angiography, and exploratory thoracotomy.

Differential Diagnosis
The differential diagnosis of congenital lobar emphysema includes pneumothorax, pneumatocele, atelectasis with compensatory hyperinflation, diaphragmatic hernia, and congenital cystic adenomatoid malformation. The most common site of involvement is the left upper lobe (42%) or right middle lobe (35%). Evaluation must differentiate regional obstructive emphysema from lobar hyperinflation secondary to an uncomplicated ball-valve mechanism due to extrinsic compression from a mass (i.e., bronchogenic cyst, tumor, lymphadenopathy, foreign body, pseudotumor or plasma cell granuloma, or vascular compression) or intrinsic obstruction from a mucus plug due to infection and inflammation from various causes.

Treatment
When respiratory distress is marked, a segmental or complete lobectomy is usually required. Less symptomatic older children may do equally well with or without lobectomy.

Clinical Findings

A. Symptoms and Signs
Clinically, respiratory distress is noted soon after birth. Expansion of the cysts occurs with the onset of breathing and produces compression of normal lung areas with mediastinal herniation. Breath sounds are decreased. With type 3 lesions, dullness to percussion may be present. Older patients can present with a spontaneous pneumothorax or with pneumonia-like symptoms.

CONGENITAL CYSTIC ADENOMATOID MALFORMATION
Patients with congenital cystic adenomatoid malformations, which are unilateral hamartomatous lesions, generally present with marked respiratory distress within the first days of life. This disorder accounts for 95% of cases of congenital cystic lung disease.

Right and left lungs are involved with equal frequency. These lesions originate during the first 4–6 weeks of gestation during the embryonic period of lung development. They appear as glandlike space-occupying masses or have an increase in terminal respiratory structures, forming intercommunicating cysts of various sizes, lined by cuboidal or ciliated pseudostratified columnar epithelium. The lesions may have polypoid formations of mucosa, with focally increased elastic tissue in the cyst wall beneath the bronchial type of epithelium. Air passages appear malformed and tend to lack cartilage.

There are three types of such malformations. Type 1 is most common (55%) and consists of single or multiple large cysts (> 2 cm in diameter) with features of mature lung tissue. Type 1 is amenable to surgical resection. A mediastinal shift is evident on examination or chest radiograph in 80% of patients and can mimic infantile lobar emphysema. Approximately 75% of type 1 lesions are on the right side. A survival rate of 90% is generally reported.

Type 2 lesions (40% of cases) consist of multiple small cysts (< 2 cm) resembling dilated simple bronchioles and are often (60%) associated with other anomalies, especially renal agenesis or dysgenesis, cardiac malformations, and intestinal atresia. Approximately 60% of type 2 lesions are on the left side. Mediastinal shift is evident less often (10%) than in type 1, and the survival rate is worse (40%).

Type 3 lesions consist of small cysts (< 0.5 cm). They appear as bulky, firm masses. The reported survival rate is 50%.

Recently, two additional types have been described: type 0, a malformation of the proximal tracheobronchial tree (incompatible with life), and type 4, a malformation of the distal acinus. Both types are extremely uncommon.

B. Imaging

With type 1 lesions, chest radiograph shows an intrapulmonary mass of soft tissue density with scattered radiolucent areas of varying sizes and shapes, usually with a mediastinal shift and pulmonary herniation. Placement of a radiopaque feeding tube into the stomach helps in the differentiation from diaphragmatic hernia. Type 2 lesions appear similar except that the cysts are smaller. Type 3 lesions may appear as a solid homogeneous mass filling the hemithorax and causing a marked mediastinal shift. Differentiation from sequestration is not difficult because congenital cystic adenomatoid malformations have no systemic blood supply.

Treatment

Treatment of type 1 and 3 lesions involves surgical removal of the affected lobe. Resection is often indicated because of the risk of infection and air trapping, since the malformation communicates with the tracheobronchial tree but mucous clearance is compromised. Because type 2 lesions are often associated with other severe anomalies, management may be more complex. Segmental resection is not feasible because smaller cysts may expand after removal of the more obviously affected area. Cystic adenomatoid malformations have been reported to have malignant potential; therefore, expectant management with observation alone should proceed with caution. Recent development of intrauterine surgery for congenital malformations has led to promising results.

ACQUIRED DISORDERS INVOLVING ALVEOLI

BACTERIAL PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever, cough, dyspnea.
- Abnormal chest examination (rales or decreased breath sounds).
- Abnormal chest radiograph (infiltrates, hilar adenopathy, pleural effusion).

General Considerations

Bacterial pneumonia is inflammation of the lung classified according to the infecting organism. Patients with the following problems are particularly predisposed to this disease: aspiration, immunodeficiency or immunosuppression, congenital anomalies (intrapulmonary sequestration, tracheoesophageal fistula, or cleft palate), abnormalities in clearance of mucus (CF, ciliary dysfunction, tracheomalacia, or bronchiectasis), congestive heart failure, and perinatal contamination.

Clinical Findings

A. Symptoms and Signs

The bacterial pathogen, severity of the disease, and age of the patient may cause substantial variations in the presentation of acute bacterial pneumonia. Infants may have few or nonspecific findings on history and physical examination. Immunocompetent older patients may not be extremely ill. Some patients may present with fever only or only with signs of generalized toxicity. Others may have additional symptoms or signs of lower respiratory tract disease (respiratory distress, cough, and sputum production), pneumonia (rales, decreased breath sounds, dullness to percussion, and abnormal tactile or vocal fremitus), or pleural involvement (splinting, pain, friction rub, and dullness to percussion). Some patients may have additional extrapulmonary findings, such as meningitis or abdominal pain, due to pneumonia itself. Others may have evidence of infection at other sites due to the same organism causing their pneumonia: meningitis, otitis media, sinusitis, pericarditis, epiglottitis, or abscesses.

B. Laboratory Findings

Elevated white blood cell counts (> 15,000/μL) frequently accompany bacterial pneumonia. However, a low white blood count (< 5000/μL) can be an ominous finding in this disease.

C. Imaging

Chest radiographic findings (lateral and frontal views) define bacterial pneumonia. Patchy infiltrates, atelectasis, hilar adenopathy, or pleural effusion may be observed. Radiographs should be taken in the lateral decubitus position to identify pleural fluid. Complete lobar consolidation is not a common finding in infants and children. Severity of disease may not correlate with radiographic findings. Clinical resolution precedes resolution apparent on chest radiograph.

D. Special Tests

Invasive diagnostic procedures (bronchial brushing or washing, lung puncture, or open or thoracoscopic lung biopsy) should be undertaken in critically ill patients when other means do not adequately identify the cause (see earlier section on Culture of Material from the Respiratory Tract).
**Differential Diagnosis**

The differential diagnosis of pneumonia varies with the age and immunocompetence of the host. The spectrum of potential pathogens to be considered includes aerobic, anaerobic, and acid-fast bacteria as well as *Chlamydia trachomatis*, *C. pneumoniae*, *C. psittaci*, *Coxiella burnetii* (Q fever), *Pasteurella multocida*, *Mycobacterium avium* complex, *Candida albicans*, and *Cryptococcus neoformans.* Respiratory viruses, *Legionella pneumophila*, *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and *Escherichia coli* may also be present, particularly with disease due to sinusitis (especially of the ethmoids), and septicemia—disease. Distal sites of infection—meningitis, otitis media, pulmonary infarction should also be considered.

When effusions are present, additional noninfectious disorders such as collagen diseases, neoplasm, and pulmonary infiltrates. When effusions are present, additional noninfectious disorders such as collagen diseases, neoplasm, and pulmonary infarction should also be considered.

**Complications**

Empyema may occur frequently with staphylococcal, pneumococcal, and group A β-hemolytic streptococcal disease. Distal sites of infection—meningitis, otitis media, sinusitis (especially of the ethmoids), and septicemia—may be present, particularly with disease due to *S. pneumoniae* or *H. influenzae.* Certain immunocompromised patients, such as those who have undergone splenectomy or who have hemoglobin SS or SC disease or thalassemia, are especially prone to overwhelming sepsis with these organisms. Distal infection of the bones, joints, or other organs (eg, liver abscess) may occur in certain hosts with specific organisms.

**Treatment**

Antimicrobial therapy should be guided by Gram stain of sputum, tracheobronchial secretions, or pleural fluid if available; radiographic findings; age and known or suspected immunocompetence of the host; and local epidemiologic information. Reasonable coverage for pneumonia in the sick, immunocompromised, or debilitated patient pending the results of bronchoalveolar lavage or thoracoscopic biopsy, should include cefazidime, clindamycin, vancomycin, a macrolide for *Legionella* and *Mycoplasma*, and possibly trimethoprim–sulfamethoxazole for *P. jiroveci*. Depending on the circumstances and the level of illness, empiric antifungal or antiviral therapy may be considered. In specific circumstances such as aspiration due to neurologic impairment or in patients with tracheostomies, clindamycin is indicated, pending culture and sensitivity studies, owing to the likely presence of resistant anaerobes.

Less severe pneumonias can often be treated with oral antibiotics based on the patient’s age and suspected organism. Lobar pneumonias presumed to be due to *S. pneumoniae* can be treated initially with oral β-lactams, including cefuroxime axetil, amoxicillin, or amoxicillin–clavulanate. However, persistence or worsening of symptoms within 3–5 days suggests the presence of a resistant organism, and newer quinolones, clindamycin, or vancomycin may be required. When possible, therapy can be guided by the antibiotic sensitivity pattern of the organisms isolated. (For further discussion, see Chapter 37.)

Whether a child should be hospitalized depends on his or her age, the severity of illness, the suspected organism, and the anticipated reliability of adherence to the treatment regimen at home. Home treatment is adequate for most older children. With febrile pneumonias, infants generally—and toddlers often—require admission. Moderate to severe respiratory distress, apnea, hypoxemia, poor feeding, clinical deterioration on treatment, or associated complications (large effusions, empyema, or abscess) indicate the need for immediate hospitalization. Careful follow-up within 12 hours to 5 days is often indicated in those not admitted. Cefuroxime or a macrolide, depending on the clinical picture, may be appropriate initial therapy for patients in this category.

Additional therapeutic considerations include oxygen, humidification of inspired gases, hydration and electrolyte supplementation, and nutrition. Removal of pleural fluid for diagnostic purposes is indicated initially to guide antimicrobial therapy. Many experts feel that early chest tube drainage of empyema fluid is indicated. Repeat pleural taps should be considered in the patient who has persistent high fever and respiratory symptoms in association with significant pleural effusions. The persistence of organisms in this fluid or the persistence of toxicity, malaise, anorexia, and wasting in the patient suggests the potential need for pleural decortication, a procedure that can be made less morbid by thoracoscopy in skilled hands.

Endotracheal intubation or mechanical ventilation may be indicated in patients with respiratory failure or in those too debilitated or overwhelmed to handle their secretions.

**Prognosis**

For the immunocompetent host in whom bacterial pneumonia is adequately recognized and treated, the survival rate is high. For example, the mortality rate from uncomplicated pneumococcal pneumonia is less than 1%. If the patient survives the initial illness, persistently abnormal pulmonary function following empyema is surprisingly uncommon, even when treatment has been delayed or inappropriate.
VIRAL PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Upper respiratory infection prodrome (fever, coryza, cough, hoarseness).
- Wheezing or rales.
- Myalgia, malaise, headache (older children).

General Considerations

Most pneumonias in children are caused by viruses. RSV, parainfluenza (1, 2, and 3) viruses, influenza (A and B) viruses, and human metapneumovirus are responsible for the large majority of cases. Severity of disease, severity of fever, radiographic findings, and the characteristics of cough or lung sounds do not reliably differentiate viral from bacterial pneumonias. Furthermore, such infections may coexist. However, substantial pleural effusions, pneumatoceles, abscesses, lobar consolidation with lobar volume expansion, and “round” pneumonias are generally inconsistent with viral disease.

Clinical Findings

A. Symptoms and Signs

An upper respiratory infection frequently precedes the onset of lower respiratory disease due to viruses. Although wheezing or stridor may be prominent in viral disease, cough, signs of respiratory difficulty (tachypnea, retractions, grunting, and nasal flaring), and physical findings (rales and decreased breath sounds) may not be distinguishable from those in bacterial pneumonia.

B. Laboratory Findings

The peripheral white blood cell count can be normal or slightly elevated and is not useful in distinguishing viral from bacterial disease. Rapid viral diagnostic methods—such as fluorescent antibody tests or enzyme-linked immunosorbent assay—should be performed on nasopharyngeal secretions to confirm this diagnosis in high-risk patients and for epidemiology or infection control. Rapid diagnosis of RSV infection does not preclude the possibility of concomitant infection with other pathogens.

C. Imaging

Chest radiographs frequently show perihilar streaking, increased interstitial markings, peribronchial cuffing, or patchy bronchopneumonia. Lobar consolidation or atelectasis may occur, however, as in bacterial pneumonia. Patients with adenovirus disease may have severe necrotizing pneumonias, resulting in the development of pneumatoceles. Hyperinflation of the lungs may occur when involvement of the small airways is prominent.

Differential Diagnosis

The differential diagnosis of viral pneumonia is the same as for bacterial pneumonia. Patients with prominent wheezing may have asthma, airway obstruction caused by foreign body aspiration, acute bacterial or viral tracheitis, or parasitic disease.

Complications

Viral pneumonia or laryngotracheobronchitis may predispose the patient to subsequent bacterial tracheitis or pneumonia as immediate sequelae. Bronchiolitis obliterans or severe chronic respiratory failure may follow adenovirus pneumonia. Bronchiolitis or viral pneumonia may contribute to persistent asthma in some patients. Bronchiectasis, chronic interstitial lung diseases, and unilateral hyperlucent lung (Sawyer-James syndrome) may follow measles, adenovirus, and influenzal pneumonias. Plasma cell granuloma may develop as a rare sequela to viral or bacterial pneumonia.

Treatment

General supportive care for viral pneumonia does not differ from that for bacterial pneumonia. Patients can be quite ill and should be hospitalized according to the level of their illness. Because bacterial disease often cannot be definitively excluded, antibiotics may be indicated.

Patients at risk for life-threatening RSV infections (eg, those with BPD or other severe pulmonary conditions, congenital heart disease, or significant immunocompromise) should be hospitalized and ribavirin should be considered. Rapid viral diagnostic tests may be a useful guide for such therapy (see Bronchiolitis section, earlier, regarding prevention). These high-risk patients and all children 6 months to 5 years of age should be immunized annually against influenza A and B viruses. Despite immunization, however, influenza infection can still occur. When available epidemiologic data indicate an active influenza A infection in the community, rimantadine, amantadine hydrochloride, or oseltamivir phosphate should be considered early for high-risk infants and children who appear to be infected. Children with suspected viral pneumonia should be placed in respiratory isolation.

Prognosis

Although most children with viral pneumonia recover uneventfully, worsening asthma, abnormal pulmonary function or chest radiographs, persistent respiratory insufficiency, and even death may occur in high-risk patients such as newborns or those with underlying lung, cardiac, or immunodeficiency disease. Patients with adenovirus infection or those concomitantly infected with RSV and second
pathogens such as influenza, adenovirus, cytomegalovirus, or P jiroveci also have a worse prognosis.

CHLAMYDIAL PNEUMONIAS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Cough, pharyngitis, tachypnea, rales, few wheezes, fever.
- Inclusion conjunctivitis, eosinophilia, and elevated immunoglobulins in some cases.

General Considerations
Pulmonary disease due to C trachomatis usually evolves gradually as the infection descends the respiratory tract. Infants may appear quite well despite the presence of significant pulmonary illness. Infant infections are now at epidemic proportions in urban environments worldwide. C pneumoniae is now recognized as a common cause of respiratory infections in adults and children.

Clinical Findings
A. Symptoms and Signs
About 50% of infants with C trachomatis pneumonia have active inclusion conjunctivitis or a history of it. Rhinopharyngitis with nasal discharge or otitis media may have occurred or may be currently present. Female patients may have vulvovaginitis. Cough is usually present. It can have a staccato character and resemble the cough of pertussis. The infant is usually tachypneic. Scattered inspiratory rales are commonly heard, wheezes rarely. Significant fever suggests a different or additional diagnosis.

In children C pneumoniae is a common respiratory pathogen and may cause 5–20% of all community-acquired pneumonias. Often these lower respiratory tract illnesses are mild or asymptomatic, although this can occasionally be a serious pathogen.

B. Laboratory Findings
Although patients may frequently be hypoxemic, carbon dioxide retention is not common. Peripheral blood eosinophilia (400 cells/μL) has been observed. Serum immunoglobulins are usually abnormal. IgM is virtually always elevated, IgG is high in many, and IgA is less frequently abnormal.

C trachomatis can usually be identified in nasopharyngeal washings using fluorescent antibody or culture techniques. C pneumoniae isolation can be difficult and the diagnosis is often made by serologic testing. These tests can be performed to confirm this diagnosis in difficult to diagnose or high-risk patients and for epidemiology or infection control.

C. Imaging
Chest radiographs may reveal diffuse interstitial and patchy alveolar infiltrates, peribronchial thickening, or focal consolidation. A small pleural reaction can be present. Despite the usual absence of wheezes, hyperexpansion is commonly present.

Differential Diagnosis
Bacterial, viral, and fungal (P jiroveci) pneumonias should be considered. Premature infants and those with BPD may also have chlamydial pneumonia. C pneumoniae is often accompanied by coinfection with other pathogens, particularly S pneumoniae and M pneumoniae.

Treatment
Erythromycin or sulfisoxazole therapy should be administered for 14 days. Hospitalization may be required for children with significant respiratory distress, coughing paroxysms, or posttussive apnea. Oxygen therapy may be required for prolonged periods in some patients.

Prognosis
An increased incidence of obstructive airway disease and abnormal pulmonary function tests may occur for at least 7–8 years following infection.

MYCOPLASMAL PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever.
- Cough.
- Most common in children older than age 5 years.
CHAPTER 18

General Considerations

*M. pneumoniae* is a common cause of symptomatic pneumonia in older children although it may be seen in children younger than 5 years of age. Endemic and epidemic infection can occur. The incubation period is long (2–3 weeks), and the onset of symptoms is slow. Although the lung is the primary infection site, extrapulmonary complications sometimes occur.

Clinical Findings

A. Symptoms and Signs

Fever, cough, headache, and malaise are common symptoms as the illness evolves. Although cough is usually dry at the onset, sputum production may develop as the illness progresses. Sore throat, otitis media, otitis externa, and bullous myringitis may occur. Rales are frequently present on chest examination; decreased breath sounds or dullness to percussion over the involved area may be present.

B. Laboratory Findings

The total and differential white blood cell counts are usually normal. The cold hemagglutinin titer can be determined and may be elevated during the acute presentation. A titer of 1:64 or higher supports the diagnosis. Acute and convalescent titers for *M. pneumoniae* demonstrating a fourfold or greater rise in specific antibodies confirm the diagnosis. Diagnosis of mycoplasmal pneumonia by polymerase chain reaction is becoming more readily available.

C. Imaging

Chest radiographs usually demonstrate interstitial or bronchopneumonic infiltrates, frequently in the middle or lower lobes. Pleural effusions are extremely uncommon.

Complications

Extrapulmonary involvement of the blood, central nervous system, skin, heart, or joints can occur. Direct Coombs-positive autoimmune hemolytic anemia, occasionally a life-threatening disorder, is the most common hematologic abnormality that can accompany *M. pneumoniae* infection. Coagulation defects and thrombocytopenia can also occur. Cerebral infarction, meningoencephalitis, Guillain-Barré syndrome, cranial nerve involvement, and psychosis all have been described. A wide variety of skin rashes, including erythema multiforme and Stevens-Johnson syndrome, can occur. Myocarditis, pericarditis, and a rheumatic fever–like illness can also occur.

Treatment

Antibiotic therapy with a macrolide for 7–10 days usually shortens the course of illness. Ciprofloxacin is a possible alternative. Supportive measures, including hydration, antipyretics, and bed rest, are helpful.

Prognosis

In the absence of the less common extrapulmonary complications, the outlook for recovery is excellent. The extent to which *M. pneumoniae* can initiate or exacerbate chronic lung disease is not well understood.

Complications

Extrapulmonary involvement of the blood, central nervous system, skin, heart, or joints can occur. Direct Coombs-positive autoimmune hemolytic anemia, occasionally a life-threatening disorder, is the most common hematologic abnormality that can accompany *M. pneumoniae* infection. Coagulation defects and thrombocytopenia can also occur. Cerebral infarction, meningoencephalitis, Guillain-Barré syndrome, cranial nerve involvement, and psychosis all have been described. A wide variety of skin rashes, including erythema multiforme and Stevens-Johnson syndrome, can occur. Myocarditis, pericarditis, and a rheumatic fever–like illness can also occur.

Treatment

Antibiotic therapy with a macrolide for 7–10 days usually shortens the course of illness. Ciprofloxacin is a possible alternative. Supportive measures, including hydration, antipyretics, and bed rest, are helpful.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Positive tuberculin skin test or anergic host.
- Positive culture for *Mycobacterium tuberculosis*.
- Symptoms of active disease (if present): chronic cough, anorexia, weight loss or poor weight gain, fever, night sweats.

TUBERCULOSIS (SEE ALSO CHAPTER 40)

General Considerations

Tuberculosis is a widespread and deadly disease resulting from infection with *M. tuberculosis*. The clinical spectrum of disease includes asymptomatic primary infection, calcified nodules, pleural effusions, progressive primary cavitating lesions, contiguous spread into adjacent thoracic structures, acute miliary tuberculosis, acute respiratory distress syndrome, overwhelming reactivation infection in the immunocompromised host, occult lymphohematogenous spread, and metastatic extrapulmonary involvement at almost any site. Because transmission is usually through respiratory droplets, isolated pulmonary parenchymal tuberculosis constitutes more than 85% of presenting cases. Pulmonary tuberculosis is the focus of discussion here; additional manifestations of tuberculosis are discussed in Chapter 40.

Following a resurgence in the 1980s and early 1990s, tuberculosis has declined among all age groups in the United States, including children. This trend has continued through 2006, the most recent year for which data are available. However, the disease remains a significant cause of morbidity and mortality worldwide.

Clinical Findings

A. Symptoms and Signs

Most children with tuberculosis are asymptomatic and present with a positive tuberculin skin test. Symptoms of active disease, if present, might include chronic cough, anorexia, weight loss or poor weight gain, fever, and night
sweats. Children can also present with symptoms of airway obstruction, sometimes with secondary bacterial pneumonia or airway collapse resulting from hilar adenopathy.

Because most children infected with tuberculosis are asymptomatic, a clue to infection may be contact with an individual with tuberculosis—often an elderly relative, a caregiver, or a person previously residing in a region where tuberculosis is endemic—or a history of travel to or residence in such an area. Homeless and extremely impoverished children are also at high risk, as are those in contact with high-risk adults (patients with AIDS, residents or employees of correctional institutions or nursing homes, drug users, and health care workers). Once exposed, pediatric patients at risk for developing active disease include infants and those with malnutrition, AIDS, diabetes mellitus, or immunosuppression (cancer chemotherapy or corticosteroids).

The symptoms of active disease listed previously most often occur during the first year of infection. Thereafter, infection remains quiescent until adolescence, when reactivation of pulmonary tuberculosis is common. At any stage, chronic cough, anorexia, weight loss or poor weight gain, and fever are useful clinical signs of reactivation. Of note, except in patients with complications or advanced disease, physical findings are few.

B. Tuberculin Skin Testing

A positive tuberculin skin test is defined by the size of induration as measured by a medical provider 48–72 hours after intradermal injection of 5 tuberculin units of purified protein derivative (PPD). A positive test is defined as an induration greater than or equal to 5 mm in patients who are at high risk for developing active disease (ie, immunocompromised, those with a history of a positive test or radiograph, children younger than 4 years, and those known to have close contact with someone with active disease); greater than 10 mm in patients from or exposed to high-risk populations (ie, born in countries with a high prevalence, users of injected drugs, having poor access to health care, or living in facilities such as jails, homeless shelters, or nursing homes); and greater than 15 mm in those who are at low risk. Tine tests should not be used. Appropriate control skin tests, such as those for hypersensitivity to diphtheria-tetanus, mumps, or *Candida albicans*, should be applied in patients with suspected or proven immunosuppression or in those with possible severe disseminated disease. If the patient fails to respond to PPD, the possibility of tuberculosis is not excluded.

In suspected cases, the patient, immediate family, and suspected carriers should also be tuberculin-tested. Because healing—rather than progression—is the usual course in the uncompromised host, a positive tuberculin test may be the only manifestation. The primary focus (usually single) and associated nodal involvement may not be seen radiographically. For patients born outside the United States or those who have received a previous bacillus Calmette-Guérin immunization, induration greater than 5 mm should be considered positive and further evaluated.

C. Laboratory Findings and Imaging

Anteroposterior and lateral chest radiographs should be obtained in all suspected cases. Culture for *M tuberculosis* is critical for proving the diagnosis and for defining drug susceptibility. Early morning gastric lavage following an overnight fast should be performed on three occasions in infants and children with suspected active pulmonary tuberculosis before treatment is started, when the severity of illness allows. Although stains for acid-fast bacilli on this material are of little value, this is the ideal culture site. Despite the increasing importance of isolating organisms because of multiple drug resistance, only 40% of children will yield positive cultures.

Sputum cultures from older children and adolescents can also be useful. Stains and cultures of bronchial secretions can be obtained using bronchoscopy. When pleural effusions are present, pleural biopsy for cultures and histopathologic examination for granulomas or organisms provide diagnostic information. Meningeal involvement is also possible in young children, and lumbar puncture should be considered in their initial evaluation.

Differential Diagnosis

Fungal diseases that affect mainly the lungs, such as histoplasmosis, coccidioidomycosis, cryptococcosis, and North American blastomycosis, may resemble tuberculosis and in cases where the diagnosis is unclear, should be excluded by biopsy or appropriate serologic studies. Atypical tuberculous organisms may involve the lungs, especially in the immunocompromised patient. Depending on the presentation, diagnoses such as lymphoreticular and other malignancies, collagen-vascular disorders, or other pulmonary infections may be considered.

Complications

In addition to those complications listed in the sections on general considerations and clinical findings, lymphadenitis, meningitis, osteomyelitis, arthritis, enteritis, peritonitis, and renal, ocular, middle ear, and cutaneous disease may occur. Infants born to parents infected with *M tuberculosis* are at great risk for developing illness. The possibility of life-threatening airway compromise must always be considered in patients with large mediastinal or hilar lesions.

Treatment

Because the risk of hepatitis due to isoniazid is extremely low in children, this drug is indicated in those with a positive tuberculin skin test. This greatly reduces the risk of subsequent active disease and complications with minimal morbidity. Isoniazid plus rifampin treatment for 6 months, plus pyrazinamide during the first 2 months, is indicated when the chest radiograph is abnormal or when extrapulmonary disease is present. Without pyrazinamide, isoniazid plus
Chronic aspiration, diffuse wheezing may occur. Generalized rales may also be present. Such patients may not develop acute febrile pneumonias.

B. Laboratory Findings and Imaging

Chest radiographs may reveal lobar consolidation or atelectasis and focal or generalized alveolar or interstitial infiltrates. In some patients with chronic aspiration, perihilar infiltrates with or without bilateral air trapping may be seen.

In severely ill patients with acute febrile illnesses, and especially when the pneumonia is complicated by a pleural effusion, a bacteriologic diagnosis should be made. In addition to blood cultures and cultures of the pleural fluid, cultures of tracheobronchial secretions and bronchoalveolar lavage specimens may be considered (see earlier section on Culture of Material from the Respiratory Tract).

In patients with chronic aspiration pneumonitis, documentation of aspiration as the cause of illness may be elusive. Barium contrast studies using liquids of increasing consistency may provide evidence of suck-swallow dysfunction or laryngeal cleft. Bolus barium swallow studies with good distention of the esophagus may help to identify an occult tracheoesophageal fistula. Gastroesophageal reflux may be a risk factor for aspiration while the child is sleeping, and an overnight or 24-hour esophageal pH probe studies may also help establish the diagnosis of gastroesophageal reflux. Although radionuclide scans are commonly used, the yield from such studies is disappointingly low. Rigid bronchoscopy in infants or flexible bronchoscopy in older children can be used to identify anatomic abnormalities such as tracheal cleft and tracheoesophageal fistula. Flexible bronchoscopy and bronchoalveolar lavage specimens to search for lipid-laden macrophages can also suggest chronic aspiration.

Clinical Findings

A. Symptoms and Signs

Acute onset of fever, cough, respiratory distress, or hypoxemia in a patient at risk suggests aspiration pneumonia. Chest physical findings, such as rales, rhonchi, or decreased breath sounds, may initially be limited to the lung region into which aspiration occurred. Although any region may be affected, the right side—especially the right upper lobe in the supine patient—is commonly affected. In patients with
rent pneumonia (eg, immunodeficiencies, ciliary dysfunction, or foreign body), chronic wheezing, or interstitial lung disorders (see next section), depending on the presentation.

**Complications**

Empyema or lung abscess may complicate acute aspiration pneumonia. Chronic aspiration may also result in bronchiectasis.

**Treatment**

Antimicrobial therapy for acute aspiration pneumonia includes coverage for gram-negative anaerobic organisms. In general, clindamycin is appropriate initial coverage. However, in some hospital-acquired infections, additional coverage for multiple resistant *P aeruginosa*, streptococci, and other organisms may be required.

Treatment of recurrent and chronic aspiration pneumonia may include the following: surgical correction of anatomic abnormalities; improved oral hygiene; improved hydration; and inhaled bronchodilators, chest physical therapy, and suctioning. In patients with compromise of the central nervous system, exclusive feeding by gastrostomy and (in some) tracheostomy may be required to control airway secretions. Gastroesophageal reflux, if present in these patients, also often requires surgical correction.

**Prognosis**

The outlook is directly related to the disorder causing aspiration.

**General Considerations**

Children’s Interstitial Lung Disease (chILD) syndrome is a constellation of signs and symptoms and not a specific diagnosis. Once recognized, chILD syndrome should elicit a search for a more specific rare ILD. Known disorders can present as chILD syndrome and must be excluded as the primary cause of symptoms. These disorders include CF, cardiac disease, asthma, acute infection, immunodeficiency, neuromuscular disease, scoliosis, thoracic cage abnormality, typical BPD or premature respiratory distress syndrome, and confirmed significant aspiration on a swallow study. However, if patients present with symptoms out of proportion to the diagnosis, consideration should be given to other ILD disorders.

**Clinical Findings**

**A. Symptoms and Signs**

chILD syndrome may present acutely in the newborn period with respiratory failure or gradually over time with a chronic dry cough or a history of dyspnea on exertion. The child with more advanced disease may have increased dyspnea, tachypnea, retractions, cyanosis, clubbing, failure to thrive, or weight loss.

**B. Diagnostic Studies**

Once chILD syndrome is recognized, initial evaluations should be directed at ruling out known conditions. The initial evaluations should include the following diagnostic studies: radiographs, barium swallow, pulmonary function tests, and skin tests (see earlier section on Tuberculosis); complete blood count and erythrocyte sedimentation rate; sweat chloride test for CF; electrocardiogram or echocardiogram; serum immunoglobulins and other immunologic evaluations; sputum studies (see later section on Pneumonia in the Immunocompromised Host); and possibly studies for Epstein-Barr virus, cytomegalovirus, *M pneumoniae*, *Chlamydia*, *Pneumocystis*, and *Ureaplasma urealyticum*.

Chest radiographs are normal in up to 10–15% of patients. Frequently, specific chILD disorders can be sus-
pected by findings on controlled volume inspiratory and expiratory high-resolution CT, which should be considered early in the course of evaluation. Infants and children younger than age 5 years require sedation, which allows either infant pulmonary function testing or bronchoscopy evaluations to be completed at the same time.

On pulmonary function testing, multiple patterns can be seen depending on the specific ILD condition such as (1) a restrictive pattern of decreased lung volumes, compliance, and carbon monoxide diffusing capacity; (2) an obstructive pattern with hyperinflation, or (3) a mixed obstructive-restrictive pattern. Infant pulmonary function testing can provide insight into pulmonary mechanics and different chILD disorders. Exercise-induced or nocturnal hypoxemia is often the earliest detectable abnormality of lung function in children.

During the second evaluation phase, bronchoscopy is performed to exclude anatomic abnormalities, obtain multiple bronchial brushings to examine cilia if ciliary dysfunction is considered a possibility, and obtain bronchoalveolar lavage for microbiologic and cytologic testing.

In patients with static or slowly progressing disease, one can then await results of bronchoscopic studies. In patients with acute, rapidly progressive disease, this stage should be combined with video-assisted thoracoscopic biopsy. Lung biopsy is the most reliable method for definitive diagnosis when analyzed by pathologists experienced in chILD disorders. A new chILD histology classification has been proposed to improve diagnostic yields. Tissue should be processed in a standard manner for special stains and cultures, electron microscopy, and immunofluorescence for immune complexes if indicated. Although transbronchial biopsy may be useful in diagnosing a few diffuse disorders and graft rejection in transplantation (eg, sarcoidosis), its overall usefulness in chILD is limited at this time.

C. Genetic Testing

Genomic mutational analysis of tissue or blood for surfactant proteins B and C (SP-B, SP-C) and ABCA3 is now offered in clinical laboratories and should be considered in most patients with diffuse lung disease or a strong family history of ILD.

Differential Diagnosis

chILD syndrome is composed of a group of diverse conditions that can differ from adult ILD conditions. Common adult causes of ILD such as UIP (usual interstitial pneumonitis, also known as idiopathic pulmonary fibrosis), which is associated with a high mortality rate, and respiratory bronchiolitis, associated with smoking, have not been found in children. Conversely, newly identified conditions unique to infancy such as neuroendocrine cell hyperplasia of infancy (NEHI) or pulmonary interstitial glycogenosis (PIG), have not been described in adults. Other chILD conditions include the genetically recognized surfactant dysfunction mutations SP-B, SP-C, and ABCA3; developmental abnormalities; and growth disorders, especially in younger children. Older children are more likely to have SP-C or ABCA3 surfactant mutations, hypersensitivity pneumonitis, or collagen-vascular disease. Other known conditions must also be ruled out.

Complications

Respiratory failure or pulmonary hypertension with cor pulmonale may occur. Mortality and morbidity can be significant in some chILD disorders.

Treatment

Therapy for known causes of ILD such as infection, aspiration, or cardiac disorders should be directed toward the primary disorder. It must be recognized that treatment for chILD conditions is anecdotal and based on case reports and small case series. In noninflammatory chILD syndrome conditions such as neuroendocrine cell hyperplasia of infancy or developmental or growth abnormalities, treatment is supportive and may not require corticosteroids. For chILD conditions such as surfactant dysfunction mutations, pulmonary interstitial glycogenosis, hypersensitivity pneumonitis, and systemic collagen-vascular disease, patients are frequently treated initially with oral (2 mg/kg/d for 6 weeks) or monthly pulse glucocorticoids (IV doses of 10–30 mg/kg for 1–3 days). Many patients require even more protracted therapy with alternate-day prednisone. Chloroquine (5–10 mg/kg/d) may be useful in selected disorders such as desquamative interstitial pneumonitis, surfactant dysfunction mutations, or refractory disease. In refractory cases, azathioprine and cyclophosphamide may be tried. Newer antifibrotic agents such as interferon-γ, which are being investigated in adult patients with interstitial pulmonary fibrosis, have not been tried in children to date. Finally, some patients with severe disease may require long-term mechanical ventilation or lung transplantation for survival. chILD disorders should be evaluated and cared for by a multidisciplinary team experienced in chILD. The chILD Family Foundation can provide further supportive resources for families (http://www.childfoundation.us).

Prognosis

The prognosis is guarded in children with ILD due to collagen-vascular disease, surfactant dysfunction mutations, and developmental disorders (eg, alveolar-capillary dysplasia). Other conditions such as neuroendocrine cell hyperplasia of infancy and pulmonary interstitial glycogenosis have not had deaths reported.

HYPERSENSITIVITY PNEUMONIA

General Considerations

Hypersensitivity pneumonitis, or extrinsic allergic alveolitis, is a T-cell-mediated disease involving the peripheral airways, interstitium, and alveoli and presents as chILD. Both acute and chronic forms may occur. In children, the most common forms are brought on by exposure to domestic and occasionally wild birds or bird droppings (eg, pigeons, parakeets, parrots, or doves). However, inhalation of almost any organic dust (moldy hay, compost, logs or tree bark, sawdust, or aerosols from humidifiers or hot tubs) can cause disease. Methotrexate-induced hypersensitivity has also been described in a child with juvenile rheumatoid arthritis. Hot tub lung can be caused by exposure to aerosolized Mycobacterium avium complex. A high level of suspicion and a thorough history are required for diagnosis.

Clinical Findings

A. Symptoms and Signs

Episodic cough and fever can occur with acute exposures. Chronic exposure results in weight loss, fatigue, dyspnea, cyanosis, and ultimately, respiratory failure.

B. Laboratory Findings

Acute exposure may be followed by polymorphonuclear leukocytosis with eosinophilia and evidence of airway obstruction on pulmonary function testing. Chronic disease results in a restrictive picture on lung function tests. Arterial blood gases may reveal hypoxemia with a decreased PaCO2 and normal pH.

The serologic key to diagnosis is the finding of precipitins (precipitating IgG antibodies) to the organic material that contain avian proteins or fungal or bacterial antigens. Ideally, to identify avian proteins, the patient’s sera should be tested with antigens from droppings of the suspected species of bird. However, exposure may invoke precipitins without causing disease.

Bronchoscopy with bronchoalveolar lavage findings of lymphocytosis or M avium complex may be suggestive. Normal cell counts may help rule out acute hypersensitivity pneumonitis.

Differential Diagnosis

Patients with mainly acute symptoms must be differentiated from those with atopic asthma. Patients with chronic symp-
Clinical Findings

A. Symptoms and Signs
Cough, wheezing, and dyspnea are common presenting complaints. In allergic bronchopulmonary aspergillosis, fever, malaise, sputum production, and rarely hemoptysis may be present. In allergic bronchopulmonary aspergillosis, patients may present with all of these findings and occasionally produce brown mucus plugs. Anorexia, weight loss, night sweats, and clubbing can also occur.

B. Laboratory Findings and Imaging
Elevated absolute peripheral blood eosinophil counts (3000/μL and often exceeding 50% of leukocytes) are present in ABPH and allergic bronchopulmonary aspergillosis. Serum IgE levels as high as 1000–10,000 IU/mL are common. In allergic bronchopulmonary aspergillosis, the serum IgE concentration appears to correlate with activity of the disease. Stools should be examined for ova and parasites—often several times—to clarify the diagnosis. Isohemagglutinin titers are often markedly elevated in ABPH.

In allergic bronchopulmonary aspergillosis and related disorders, patients may show central bronchiectasis on chest radiograph (so-called tramlines) or CT scan. Saccular proximal bronchiectasis of the upper lobes is pathognomonic. Although the chest radiograph may be normal, peribronchial haziness, focal or platelike atelectasis, or patchy consolidation can occur. Positive immediate skin tests, serum IgG precipitating antibodies, or IgE specific for the offending fungus is present.

Differential Diagnosis
These disorders must be differentiated from exacerbations of asthma, CF, or other underlying lung disorders that cause infiltrates to appear on chest radiographs. Allergic bronchopulmonary aspergillosis can occur in patients with CF.

Complications
Delayed recognition and treatment of allergic bronchopulmonary aspergillosis may cause progressive lung damage and bronchiectasis. Lesions of the conducting airways in bronchocentric granulomatosis can extend into adjacent lung parenchyma and pulmonary arteries, resulting in secondary vasculitis.

Treatment
Therapy for the specific parasite causing ABPH should be given, and corticosteroids may be required when illness is severe. Treatment of disease due to microfilariae is both diagnostic and therapeutic. Allergic bronchopulmonary aspergillosis and related disorders are treated with prolonged courses of oral corticosteroids, bronchodilators, and chest physical therapy. In patients with CF, itraconazole may decrease corticosteroid doses for those with allergic bronchopulmonary aspergillosis. Pulmonary vasculitis associated with collagen-vascular disease is usually treated with high-dose steroids or cytotoxic agents.

PNEUMONIA IN THE IMMUNOCOMPROMISED HOST

General Considerations
Immunocompromised children can present with focal pneumonia or ILD. Pneumonia in an immunocompromised host may be due to any common bacteria (streptococci, staphylococci, or M pneumoniae) or less common pathogens such as Toxoplasma gondii, P jiroveci, Aspergillus species, Mucor, Candida species, Cryptococcus neoformans, gram-negative enteric and anaerobic bacteria, Nocardia, Legionella pneumophila, mycobacteria, and viruses (cytomegalovirus, varicella-zoster, herpes simplex, influenza virus, RSV, human metapneumovirus, or adenovirus). Multiple organisms are commonly present.

Clinical Findings
A. Symptoms and Signs
Patients often present with subtle signs such as mild cough, tachypnea, or low-grade fever that can rapidly progress to high fever, respiratory distress, and hypoxemia or chILD syndrome. An obvious portal of infection, such as an intravascular catheter, may predispose to bacterial or fungal infection.

B. Laboratory Findings and Imaging
Fungal, parasitic, or bacterial infection, especially with antibiotic-resistant bacteria, should be suspected in the neutropenic child. Cultures of peripheral blood, sputum, tracheobronchial secretions, urine, nasopharynx or sinuses, bone marrow, pleural fluid, biopsied lymph nodes, or skin lesions or cultures through intravascular catheters should be obtained as soon as infection is suspected.

Invasive methods are commonly required to make a diagnosis. Appropriate samples should be obtained soon after a patient with pneumonia fails to respond to initial treatment. The results of these procedures usually lead to important changes in empiric preoperative therapy. Sputum is often unavailable. Bronchoalveolar lavage frequently provides the diagnosis of one or more organisms and should be done early in evaluation. The combined use of a wash, brushing, and lavage has a high yield. In patients with rapidly
advancing disease, lung biopsy becomes more urgent. The morbidity and mortality of this procedure can be reduced by a surgeon skilled in video-assisted thoracoscopic surgical (VATS) techniques. Because of the multiplicity of organisms that may cause disease, a comprehensive set of studies should be done on lavage and biopsy material. These consist of rapid diagnostic studies, including fluorescent antibody studies for Legionella; rapid culture and antigen detection for viruses; Gram, acid-fast, and fungal stains; cytologic examination for viral inclusions; cultures for viruses, anaerobic and aerobic bacteria, fungi, mycobacteria, and Legionella; and rapid immunofluorescent studies for P jiroveci.

Chest radiographs and increasingly high-resolution CT scans may be useful in identifying the pattern and extent of disease. In P jiroveci pneumonia, dyspnea and hypoxemia may be marked despite minimal radiographic abnormalities.

### Differential Diagnosis

The organisms causing disease vary with the type of immunocompromise present. For example, the splenectomized patient may be overwhelmed by infection with S pneumoniae or H influenzae. The infant receiving adrenocorticotropic hormone therapy may be more likely to have P jiroveci infection. The febrile neutropenic child who has been receiving adequate doses of intravenous broad-spectrum antibiotics may have fungal disease. The key to diagnosis is to consider all possibilities of infection.

Depending on the form of immunocompromise, perhaps only half to two thirds of new pulmonary infiltrates in such patients represents infection. The remainder are caused by pulmonary toxicity of radiation, chemotherapy, or other drugs; pulmonary disorders, including hemorrhage, embolism, atelectasis, aspiration, idiopathic pneumonia syndrome in bone marrow transplant patients, or acute respiratory distress syndrome; recurrence or extension of primary malignant growths or immunologic disorders; transfusion reactions, leukostasis, or tumor cell lysis; or interstitial lung disease, such as lymphocytic interstitial pneumonitis with HIV infection.

### Complications

Progressive respiratory failure, shock, multiple organ damage, disseminated infection, and death commonly occur in the infected immunocompromised host if the primary etiology is not treated effectively.

### Treatment

Broad-spectrum intravenous antibiotics are indicated early in febrile, neutropenic, or immunocompromised children. Trimethoprim–sulfamethoxazole (for Pneumocystis) and macrolides (for Legionella) are also indicated early in the treatment of immunocompromised children before an organism is identified. Further therapy should be based on studies of specimens obtained from bronchoalveolar lavage or lung biopsy. Recent data suggest that use of noninvasive ventilation strategies early in the course of pulmonary insufficiency or respiratory failure may decrease mortality.

### Prognosis

Prognosis is based on the severity of the underlying immunocompromise, appropriate early diagnosis and treatment, and the infecting organisms. Intubation and mechanical ventilation have been associated with high mortality rates, especially in bone marrow transplant patients.

---

---

### LUNG ABSCESS

#### General Considerations

Lung abscesses are most likely to occur in immunocompromised patients; in those with severe infections elsewhere (embolic spread); or in those with recurrent aspiration, malnutrition, or blunt chest trauma. Although organisms such as S aureus, H influenzae, S pneumoniae, and viridans streptococci more commonly affect the previously normal host, anaerobic and gram-negative organisms as well as Nocardia, Legionella species, and fungi (Candida and Aspergillus) should also be considered in the immunocompromised host.

#### Clinical Findings

##### A. Symptoms and Signs

High fever, malaise, and weight loss are often present. Symptoms and signs referable to the chest may or may not be present. In infants, evidence of respiratory distress can be present.

##### B. Laboratory Findings and Imaging

Elevated peripheral white blood cell count with a neutrophil predominance or an elevated erythrocyte sedimentation rate may be present. Blood cultures are rarely positive except in the overwhelmed host.

Chest radiographs usually reveal single or multiple thick-walled lung cavities. Air-fluid levels can be present. Local compressive atelectasis, pleural thickening, or adenopathy may also occur. Chest CT scan may provide better localization and understanding of the lesions.
In patients producing sputum, stains and cultures may provide the diagnosis. Direct percutaneous aspiration of material for stains and cultures guided by fluoroscopy or ultrasonography should be considered in the severely compromised or ill.

### Differential Diagnosis

Loculated pyopneumothorax, an *Echinococcus* cyst, neoplasms, plasma cell granuloma, and infected congenital cysts and sequestrations should be considered. Pneumatoceles, non–fluid-filled cysts, are common in children with empyema and usually resolve over time.

### Complications

Although complications due to abscesses are now rare, mediastinal shift, tension pneumothorax, and spontaneous rupture can occur. Diagnostic maneuvers such as lung puncture may also cause complications (pneumothorax).

### Treatment

Because of the risks of lung puncture, uncomplicated abscesses are frequently conservatively treated in the uncompromised host with appropriate broad-spectrum antibiotics directed at *S. aureus*, *H. influenzae*, and streptococci. Additional coverage for anaerobic and gram-negative organisms should be provided for others. Prolonged therapy (3 weeks or more) may be required. Attempts to drain abscesses via bronchoscopy have caused life-threatening airway compromise. Surgical drainage or lobectomy is occasionally required, primarily in immunocompromised patients. However, such procedures may themselves cause life-threatening complications.

### Prognosis

Although radiographic resolution may be very slow, resolution occurs in most patients without risk factors for lower respiratory tract infections or loss of pulmonary function. In the immunocompromised host, the outlook depends on the underlying disorder.

---

**DISEASES OF THE PULMONARY CIRCULATION**

**PULMONARY HEMORRHAGE**

### General Considerations

Pulmonary hemorrhage is caused by a spectrum of disorders affecting the large and small airways and alveoli. It can occur as an acute or chronic process. Hemorrhage involving the alveoli is termed diffuse alveolar hemorrhage. If pulmonary hemorrhage is subacute or chronic, hemosiderin-laden macrophages are found in the sputum and tracheal or gastric aspirate. Many cases are secondary to infection (bacterial, mycobacterial, parasitic, viral, or fungal), lung abscess, bronchiectasis (CF or other causes), foreign body, coagulopathy (often with overwhelming sepsis), or elevated pulmonary venous pressure (secondary to congestive heart failure or anatomic heart lesions). Other causes include lung contusion from trauma, arteriovenous fistula, multiple telangiectasias, pulmonary sequestration, agenesis of a single pulmonary artery, and esophageal duplication or bronchogenic cyst. Rarer causes are tumors (eg, bronchial adenoma or left atrial myxoma) and pulmonary infarction secondary to pulmonary embolus.

Diffuse alveolar hemorrhage may be idiopathic or drug-related or may occur in Goodpasture syndrome, rapidly progressive glomerulonephritis, and systemic vasculitides (often associated with such collagen-vascular diseases as systemic lupus erythematosus, rheumatoid arthritis, Wegener granulomatosis, polyarteritis nodosa, Henoch-Schönlein purpura, and Behçet’s disease). Idiopathic pulmonary hemosiderosis refers to the accumulation of hemosiderin in the lung, especially the alveolar macrophage, as a result of chronic or recurrent hemorrhage (usually from pulmonary capillaries) that is not associated with the previously listed causes. Children and young adults are mainly affected, with the age at onset ranging from 6 months to 20 years. This group of disorders includes milk allergy in young infants (Heiner syndrome).

Several cases of pulmonary hemorrhage and pulmonary hemosiderosis have been reported in infants exposed to a toxigenic mold, *Stachybotrys chartarum*, and other fungi. This association was initially noted in Cleveland, Ohio. The infants were primarily African American, living in older homes, and often the homes had recent water damage. Environmental tobacco smoke was also frequently present in the environment. Other forms of hypersensitivity pneumonitis have also been reported to cause pulmonary bleeding.

### Clinical Findings

#### A. Symptoms and Signs

Pulmonary hemorrhage has as many symptoms as it has causes. Large airway hemorrhage presents with hemoptyis and symptoms of the underlying cause, such as infection, foreign body, or bronchiectasis in CF. Hemoptyis from larger airways is often bright red or contains clots. Idiopathic pulmonary hemosiderosis usually presents with nonspecific respiratory symptoms (cough, tachypnea, and retractions) with or without hemoptyis, poor growth, and fatigue. Some children or young adults may present with massive hemoptyis, marked respiratory distress, stridor, or a pneumonia-like syndrome. Fever, abdominal pain, digital clubbing, and chest pain may be reported. Jaundice and hepatosplenomegaly may be present with chronic bleeding. Physical examination often reveals decreased breath sounds, rales, rhonchi, or wheezing.
B. Laboratory Findings and Imaging

Laboratory studies vary depending on the cause of hemorrhage. Following long-standing idiopathic pulmonary hemorrhage, iron deficiency anemia and heme-positive sputum are present. Nonspecific findings may include lymphocytosis and an elevated erythrocyte sedimentation rate. Peripheral eosinophilia is present in up to 25% of patients. Chest radiographs demonstrate a range of findings, from transient perihilar infiltrates to large, fluffy alveolar infiltrates with or without atelectasis and mediastinal adenopathy. Pulmonary function testing generally reveals restrictive impairment, with low lung volumes, poor compliance, and an increased diffusion capacity. Hemosiderin-laden macrophages are found in bronchial or gastric aspirates. The diagnostic usefulness of lung biopsy is controversial.

Diffuse alveolar hemorrhage with underlying systemic disease such as systemic lupus erythematosus, Wegener granulomatosis, and occasionally Goodpasture syndrome can occur with the histologic entity known as necrotizing pulmonary capillaritis. On lung biopsy the alveolar septa are infiltrated with neutrophils, and alveolar hemorrhage is acute or chronic. The septa can fill with edema or fibrinoid necrosis. Idiopathic pulmonary hemosiderosis may represent a mild form of capillaritis associated with alveolar hemorrhage. It might represent a process that waxes and wanes, and capillaritis may be focal or mild. Likewise, an immune-mediated process may cause idiopathic pulmonary hemosiderosis, although no serologic marker has yet been identified. Although capillaritis has been described without evidence of underlying systemic disease, the search for collagen-vascular disease, vasculitis, or pulmonary fibrosis should be exhaustive.

The investigation should include serologic studies such as circulating antineutrophilic cytoplasmic autoantibodies for Wegener granulomatosis, perinuclear antineutrophilic cytoplasmic autoantibodies for microscopic polyangiitis, antinuclear antibodies for systemic lupus erythematosus, and anti-basement membrane antibodies for Goodpasture syndrome. α1-Antitrypsin deficiency has been associated with vasculitides and should be considered.

Suspected cases of cow’s milk–induced pulmonary hemosiderosis can be confirmed by laboratory findings that include high titers of serum precipitins to multiple constituents of cow’s milk and positive intradermal skin tests to various cow’s milk proteins. Improvement after an empiric trial of a diet free of cow’s milk also supports the diagnosis.

Differential Diagnosis

The search for the site of respiratory bleeding, underlying systemic illness, and cardiac or vascular abnormalities will help define the diagnosis. When gross hemoptysis is present, large airway bronchiectasis, epistaxis, foreign body, and arteriovenous or pulmonary malformations should be ruled out. MRI or CT-assisted angiography can localize abnormal or systemic arterial flow.

Alveolar bleeding with hemoptysis is often frothy and pink. The differential diagnosis includes the disorders causing diffuse alveolar hemorrhage listed earlier. In contrast to idiopathic pulmonary hemosiderosis, Goodpasture syndrome occurs in a slightly older age group (15–35 years), tends to have a more aggressive pulmonary course, and has renal involvement (crescentic proliferative glomerulonephritis and circulating antiglomerular basement membrane antibody). Wegener granulomatosis also has renal involvement (granulomatous glomerulitis with necrotizing vasculitis, but renal biopsy findings may be nonspecific) and other systemic manifestations, especially with upper and lower respiratory tract inflammation. Upper tract involvement includes sinusitis, rhinitis, recurrent epistaxis, otitis media, saddle-nose deformity, and subglottic stenosis. Wegener granulomatosis may occur without renal involvement early in the course of the disease. The diagnosis can be made based on biopsy findings or an elevated circulating antineutrophilic cytoplasmic autoantibody titer.

Treatment

Therapy should be aimed at direct treatment of the underlying disease. Supportive measures, including iron therapy, supplemental oxygen, and blood transfusions, may be needed. A diet free of cow’s milk should be tried in infants. Systemic corticosteroids have been used for various causes of diffuse alveolar hemorrhage and have been particularly successful in those secondary to collagen-vascular disorders and vasculitis. Case reports have been published describing the variable effectiveness of steroids, chloroquine, cyclophosphamide, and azathioprine for idiopathic pulmonary hemosiderosis.

Prognosis

The outcome of idiopathic pulmonary hemosiderosis is variable, characterized by a waxing and waning course of intermittent intrapulmonary bleeds and the gradual development of pulmonary fibrosis over time. The severity of the underlying renal disease contributes to the mortality rates associated with Goodpasture syndrome and Wegener granulomatosis. Diffuse alveolar hemorrhage is considered a lethal pulmonary complication of systemic lupus erythematosus.

PULMONARY EMBOLISM

A. Symptoms and Signs

Pulmonary embolism usually presents clinically as an acute onset of dyspnea and tachypnea. Heart palpitations or a sense of impending doom may be reported.

Pleuritic chest pain and hemoptysis may be present (not common), along with splinting, cyanosis, and tachycardia. Massive emboli may be present with syncope and cardiac arrhythmias. Physical examination is usually normal (except for tachycardia and tachypnea) unless the embolism is associated with an underlying disorder. Mild hypoxemia, rales, focal wheezing, or a pleural friction rub may be found.

B. Laboratory Findings and Imaging

Radiographic findings may be normal, but a peripheral infiltrate, small pleural effusion, or elevated hemidiaphragm can be present. If the emboli are massive, differential blood flow and pulmonary artery enlargement may be appreciated. The electrocardiogram is usually normal unless the pulmonary embolus is massive. Echocardiography is useful in detecting the presence of a large proximal embolus. A negative D-dimer has a more than 95% negative predictive value for an embolus. Ventilation-perfusion scans show localized areas of ventilation without perfusion.

Spiral CT with contrast may be helpful, but pulmonary angiography is the gold standard. Further evaluation may include Doppler ultrasound studies of the legs to search for deep venous thrombosis. Coagulation studies, including assessments of antithrombin III and protein C or S deficiencies or defective fibrinolysis may be indicated. Antiphospholipid antibodies and other coagulation regulatory proteins (proteins C and S, and factor V Leiden) should be checked, as abnormalities have been demonstrated in 70% of the hematology referrals in one pediatric institution.

Treatment

Acute treatment includes supplemental oxygen, sedation, and anticoagulation. Current recommendations include heparin administration to maintain an activated partial thromboplastin time that is 1.5 or more times the control value for the first 24 hours. Urokinase (2000–4000 units/kg for 36 hours) can be used to help dissolve the embolus. Tissue plasminogen activator is another option via central or peripheral administration. These therapies should be followed by warfarin therapy for at least 6 weeks with an international normalized ratio (INR) greater than 2. In patients with identifiable deep venous thrombosis of the lower extremities and significant pulmonary emboli (with hemodynamic compromise despite anticoagulation), inferior vena caval interruption may be necessary. However, long-term prospective data regarding this latter therapy are lacking.

Bounameaux H: Review: ELISA D-dimer is sensitive but not specific in diagnosing pulmonary embolism in an ambulatory clinical setting. ACP J Club 2003;138:24 [PMID: 12511136].

PULMONARY EDEMA

General Considerations

Pulmonary edema is excessive accumulation of extravascular fluid in the lungs. This occurs when fluid is filtered into the lungs faster than it can be removed, leading to changes in lung mechanics such as decreased lung compliance, worsening hypoxemia from ventilation-perfusion mismatch, bronchial compression, and if advanced, decreased surfactant function. There are two basic types of pulmonary edema: increased pressure (cardiogenic or hydrostatic) and increased permeability (noncardiogenic or primary). Hydrostatic pulmonary edema is usually due to excessive increases in pulmonary venous pressure, which is most commonly due to congestive heart failure from multiple causes. In contrast, many lung diseases, especially acute respiratory distress syndrome, are characterized by the development of pulmonary
edema secondary to changes in permeability due to injury to the alveolocapillary barrier. In these settings, pulmonary edema occurs independently of the elevations of pulmonary venous pressure.

Clinical Findings

A. Symptoms and Signs

Cyanosis, tachypnea, tachycardia, and respiratory distress are commonly present. Physical findings include rales, diminished breath sounds, and (in young infants) expiratory wheezing. More severe disease is characterized by progressive respiratory distress with marked retractions, dyspnea, and severe hypoxemia.

B. Imaging

Chest radiographic findings depend on the cause of the edema. Pulmonary vessels are prominent, often with diffuse interstitial or alveolar infiltrates. Heart size is usually normal in permeability edema but enlarged in hydrostatic edema.

Treatment

Although specific therapy depends on the underlying cause, supplemental oxygen therapy is indicated and, if needed, ventilator support for respiratory failure. Diuretics, digoxin, and vasodilators may be indicated for congestive heart failure along with restriction of salt and water. Recommended interventions for permeability edema are reduction of vascular volume and maintenance of the lowest central venous or pulmonary arterial wedge pressure possible without sacrificing cardiac output or causing hypotension (see following discussion). β-Adrenergic agonists such as terbutaline have been shown to increase alveolar clearance of lung water, perhaps through the action of a sodium-potassium channel pump. Maintaining normal albumin levels and a hematocrit concentration above 30 maintains the filtration of lung liquid toward the capillaries, avoiding low oncotic pressure.

CONGENITAL PULMONARY LYMPHANGIECTASIA

General Considerations

Structurally, congenital pulmonary lymphangiectasia appears as dilated subpleural and interlobular lymphatic channels and may present as part of a generalized lymphangiectasis (in association with obstructive cardiovascular lesions—especially total anomalous pulmonary venous return) or as an isolated idiopathic lesion. Pathologically, the lung appears firm, bulky, and noncompressible, with prominent cystic lymphatics visible beneath the pleura. On cut section, dilated lymphatics are present near the hilum, along interlobular septa, around bronchovascular bundles, and beneath the pleura. Histologically, dilated lymphatics have a thin endothelial cell lining overlying a delicate network of elastin and collagen.

Clinical Findings

Congenital pulmonary lymphangiectasia is a rare, usually fatal disease that generally presents as acute or persistent respiratory distress at birth. Although most patients do not survive the newborn period, some survive longer, and there are isolated case reports of its diagnosis later in childhood. It may be associated with features of Noonan syndrome, asplenia, total anomalous pulmonary venous return, septal defects, atrioventricular canal, hypoplastic left heart, aortic arch malformations, and renal malformations. Chylothorax has been reported. Chest radiographic findings include a ground-glass appearance, prominent interstitial markings suggesting lymphatic distention, diffuse hyperlucency of the pulmonary parenchyma, and hyperinflation with depression of the diaphragm.

Prognosis

Although the onset of symptoms may be delayed for as long as the first few months of life, prolonged survival is extremely rare. Most deaths occur within weeks after birth. Rapid diagnosis is essential in order to expedite the option of pulmonary transplantation.

EVENTRATION OF THE DIAPHRAGM

Eventration of the diaphragm occurs when striated muscle is replaced with connective tissue and is demonstrated on radiograph by elevation of part or all of the diaphragm. There are two types: congenital and acquired. The congenital type is thought to represent incomplete formation of the diaphragm in utero. The acquired type is related to atrophy of diaphragm muscles secondary to prenatal or postnatal phrenic nerve injury. The differential diagnosis of eventration includes phrenic nerve injury and partial diaphragmatic hernia. Small eventrations may be an incidental finding on a chest radiograph, commonly seen on the right side. Ultrasound provides useful information to further define a suspected eventration. When defects are small, there is no
paradoxical movement of the diaphragm and little symptomatology. When defects are large, paradoxical movement of the diaphragm may be present. The degree of respiratory distress depends in large part on the amount of paradoxical motion of the diaphragm. When the diaphragm moves upward during inspiration, instability of the inferior border of the chest wall increases the work of breathing and can lead to respiratory muscle fatigue and potential failure when stressed. Symptoms include persistent increased work of breathing, particularly with feeding or failure to extubate.

Treatment is based on severity of symptoms. If symptoms persist for 2–4 weeks, the diaphragm is surgically plicated, which stabilizes it. Function returns to the diaphragm in about 50% of cases of phrenic nerve injury whether or not plication was performed. Recovery periods of up to 100 days have been reported in these cases.

Surgical literature is providing more information regarding long-term outcomes following repair. Timing of repair is critical in light of growth plate maturation. Pectus excavatum may be associated with congenital heart disease.

Pectus carinatum is a protrusion of the upper or lower (more common) portion of the sternum, more commonly seen in males. Again, although the disorder may have a psychological impact, impedance of cardiopulmonary function is debated. The decision to repair this deformity is often based on cosmetic grounds, but research has shown that those with reduced endurance or dyspnea with mild exercise experienced marked improvement within 6 months following repair, suggesting possible physiologic indications. Pectus carinatum may be associated with systemic diseases such as the mucopolysaccharidoses and congenital heart disease.

Neuromuscular disorders are discussed in detail in Chapter 23. Weakness of the respiratory and pharyngeal muscles leads to chronic or recurrent pneumonia secondary to aspiration and infection, atelectasis, hypoventilation, and respiratory failure in severe cases. Scoliosis, which frequently accompanies longstanding neuromuscular disorders, may further compromise respiratory function. Typical physical findings are a weak cough, decreased air exchange, crackles, wheezing, and dullness to percussion. Signs of cor pulmonale (loud pulmonary component to the second heart sound, hepatomegaly, and elevated neck veins) may be evident in advanced cases. Chest radiographs generally show small lung volumes. If chronic aspiration is present, increased interstitial infiltrates and areas of atelectasis or consolidation may be present. Arterial blood gases demonstrate hypoxemia in the early stages and compensated respiratory acidosis in the late stages. Typical pulmonary function abnormalities include low lung volumes and decreased inspiratory force generated against an occluded airway.

Treatment is supportive and includes vigorous pulmonary toilet, antibiotics with infection, and oxygen to correct...
The parietal pleura covers the inner surface of the chest wall. The visceral pleura covers the outer surface of the lungs. Disease processes can lead to accumulation of air or fluid in the pleural space. Pleural effusions are classified as transudates or exudates. Transudates occur when there is imbalance between hydrostatic and oncotic pressure, so that fluid filtration exceeds reabsorption (eg, congestive heart failure). Exudates form as a result of inflammation of the pleural surface leading to increased capillary permeability (eg, parapneumonic effusions). Other pleural effusions include chylothorax and hemothorax.

Thoracentesis is helpful in characterizing the fluid and providing definitive diagnosis. Recovered fluid is considered an exudate (as opposed to a transudate) if any of the following are found: a pleural fluid–serum protein ratio greater than 0.5, a pleural fluid–serum lactate dehydrogenase ratio greater than 0.6, or a pleural fluid lactate dehydrogenase level greater than 200 units/L. Important additional studies on pleural fluid include cell count; pH and glucose; Gram, acid-fast, and fungal stains; cultures; counterimmunoelectrophoresis for specific organisms; and occasionally, amylase concentration. Cytologic examination of pleural fluid should be performed to rule out leukemia or other neoplasm.

Bacterial pneumonia is often accompanied by pleural effusion. Some of these effusions harbor infection, and others are inflammatory reactions to pneumonia. The nomenclature in this area is somewhat confusing. Some authors use the term empyema for grossly purulent fluid and parapneumonic effusion for nonpurulent fluid. It is clear, however, that some nonpurulent effusions will also contain organisms and represent either partially treated or early empyema. It is probably best to refer to all effusions associated with pneumonia as parapneumonic effusions, some of which are infected and some not.

The most common organism associated with empyema is S pneumoniae. Other common organisms include H influenzae and S aureus. Less common causes are group A streptococci, gram-negative organisms, anaerobic organisms, and M pneumoniae. Effusions associated with tuberculosis are almost always sterile and constitute an inflammatory reaction.

Clinical Findings

A. Symptoms and Signs

Patients usually present with typical signs of pneumonia, including fever, tachypnea, and cough. They may have chest pain, decreased breath sounds, and dullness to percussion on the affected side and may prefer to lie on the affected side. With large effusions, there may be tracheal deviation to the contralateral side.

B. Laboratory Findings

The white blood cell count is often elevated, with left shift. Blood cultures are sometimes positive. The tuberculin skin test is positive in most cases of tuberculosis. Thoracentesis reveals findings consistent with an exudate. Cells in the pleural fluid are usually neutrophils in bacterial disease and lymphocytes in tuberculous effusions. In bacterial disease, pleural fluid pH and glucose are often low. pH less than 7.2 suggests active bacterial infection. The pH of the specimen should be determined in a blood gas syringe sent to the laboratory on ice. Extra heparin should not be used in the syringe as it can falsely lower the pH. Although in adults the presence of low pH and glucose necessitates aggressive and thorough drainage procedures, the prognostic significance of these findings in children is unknown. Gram stain, cultures, and counterimmunoelectrophoresis are often positive for the offending organism.

C. Imaging

The presence of pleural fluid is suggested by a homogeneous density that obscures the underlying lung on chest radiograph. Large effusions may cause a shift of the mediastinum to the contralateral side. Small effusions may only blunt the costophrenic angle. Lateral decubitus radiographs may help
to detect freely movable fluid by demonstrating a layering-out effect. If the fluid is loculated, no such effect is perceived. Ultrasonography can be extremely valuable in localizing the fluid and detecting loculations, especially when thoracentesis is contemplated, but availability may be limited. Chest CT scan can help determine if loculations are present and direct further care of complicated pneumonias.

**Treatment**

After initial thoracentesis and identification of the organism, appropriate intravenous antibiotics and adequate drainage of the fluid remain the mainstay of therapy, but the approach is debated. Although there is a trend toward managing smaller pneumococcal empyemas without a chest tube, most larger effusions require chest tube drainage. Often the empyema has been present for more than 7 days, increasing the chance for loculation of fluid. Evidence of early decortication using thoracoscopic techniques such as video-assisted thoracoscopic surgery (VATS) may reduce morbidity and has been shown to shorten length of hospital stay when done by an experienced surgeon. While there is growing use of VATS as first-line therapy, it is not standard of care. Aggressive management with drainage of pleural cavity fluid and release of adhesions with fibrinolytics is often sought in many institutions where the chest tube is placed in the operating room under anesthesia. The decision on therapeutic choice will vary depending on the resources available to the clinician.

**Prognosis**

The prognosis is related to the severity of disease but is generally excellent, with complete or nearly complete recovery expected in most instances.

**HEMOTHORAX**

Accumulation of blood in the pleural space can be caused by surgical or accidental trauma, coagulation defects, and pleural or pulmonary tumors. With blunt trauma, hemopneumothorax may be present. Symptoms are related to blood loss and compression of underlying lung parenchyma. There is some risk of secondary infection, resulting in empyema.

**Treatment**

Drainage of a hemothorax is required when significant compromise of pulmonary function is present, as with hemopneumothorax. In uncomplicated cases, observation is indicated because blood is readily absorbed spontaneously from the pleural space.

VATS has been used successfully in the management of hemothorax. Chest CT scan is helpful to select patients who may require surgery, as identification of blood and the volume of blood may be more predictive by this method than by chest radiograph.

**CHYLOTHORAX**

The accumulation of chyle, fluid of intestinal origin containing fat digestion products, in the pleural space usually results from accidental or surgical trauma to the thoracic duct. In the newborn, chylothorax can be congenital or secondary to birth trauma. This condition also occurs as a result of superior vena caval obstruction secondary to central venous lines and following Fontan procedures for tricuspid atresia. Symptoms of chylothorax are related to the amount of fluid accumulation and the degree of compromise of underlying pulmonary parenchyma. Thoracentesis reveals typical milky fluid (unless the patient has been fasting) containing chiefly T lymphocytes.

**Treatment**

Treatment should be conservative because many chylothoraces resolve spontaneously. Oral feedings with medium-chain triglycerides reduce lymphatic flow through the thoracic duct. Recent literature has shown somatostatin as a viable therapeutic option. Drainage of chylous effusions should be performed only for respiratory compromise because the fluid often rapidly reaccumulates. Repeated or continuous drainage may lead to protein malnutrition and T-cell depletion, rendering the patient relatively immunocompromised. If reaccumulation of fluid persists, surgical ligation of the thoracic duct or sclerosis of the pleural space can be attempted, although the results may be less than satisfactory.
alveolar spaces into the interstitial spaces of the lung. Migration to the visceral pleura ultimately leads to rupture into the pleural space. Associated conditions include pneumomediastinum, pneumopericardium, pneumoperitoneum, and subcutaneous emphysema. These conditions are more commonly associated with dissection of air into the interstitial spaces of the lung with retrograde dissection along the bronchovascular bundles toward the hilum.

**Clinical Findings**

**A. Symptoms and Signs**

The clinical spectrum can vary from asymptomatic to severe respiratory distress. Associated symptoms include cyanosis, chest pain, and dyspnea. Physical examination may reveal decreased breath sounds and hyperresonance to percussion on the affected side with tracheal deviation to the opposite side. When pneumothorax is under tension, cardiac function may be compromised, resulting in hypotension or narrowing of the pulse pressure. Pneumopericardium is a life-threatening condition that presents with muffled heart tones and shock. Pneumomediastinum rarely causes symptoms by itself.

**B. Imaging**

Chest radiographs usually demonstrate the presence of free air in the pleural space. If the pneumothorax is large and under tension, compressive atelectasis of the underlying lung and shift of the mediastinum to the opposite side may be demonstrated. Cross-table lateral and lateral decubitus radiographs can aid in the diagnosis of free air. Pneumopericardium is identified by the presence of air completely surrounding the heart, whereas in patients with pneumomediastinum, the heart and mediastinal structures may be outlined with air, but the air does not involve the diaphragmatic cardiac border. Chest CT scan may be helpful with recurrent spontaneous pneumothoraces to look for subtle pulmonary disease not seen on chest radiograph, but this is debated.

**Differential Diagnosis**

Acute deterioration of a patient on a ventilator can be caused by tension pneumothorax, obstruction or dislodgment of the endotracheal tube, or ventilator failure. Radiographically, pneumothorax must be distinguished from diaphragmatic hernia, lung cysts, congenital lobar emphysema, and cystic adenomatoid malformation, but this task is usually not difficult.

**Treatment**

Small or asymptomatic pneumothoraces usually do not require treatment and can be managed with close observation. Larger or symptomatic ones usually require drainage, although inhalation of 100% oxygen to wash out blood nitrogen can be tried. Needle aspiration should be used to relieve tension acutely, followed by chest tube or pigtail catheter placement. Pneumopericardium requires immediate identification, and if clinically symptomatic, needle aspiration to prevent death, followed by pericardial tube placement.

In older patients with spontaneous pneumothorax, recurrences are common; sclerosing and surgical procedures are often required.

**SLEEP-DISORDERED BREATHING**

**General Considerations**

Sleep apnea is recognized as a major public health problem in adults, with the risk of excessive daytime sleepiness, driving accidents, poor work performance, and effects on mental health. Pediatric sleep disorders are less commonly recognized because of a lack of training in sleep problem recognition and the presentation, risks, and outcome all differ from those in adults. The spectrum of sleep-disordered breathing includes obstructive sleep apnea, upper airway resistance disorder, and primary snoring. Sleep apnea is defined as cessation of breathing and can be classified as obstructive (the attempt to breathe through an obstructed airway) or central (the lack of effort to breathe). Snoring, mouth breathing, and upper airway obstruction are further discussed in Chapter 17.

**Clinical Findings & Differential Diagnosis**

**A. Obstructive Sleep Apnea**

Obstructive sleep apnea occurs in normal children with an incidence of about 2%, increasing in children with craniofacial abnormalities, neuropathies, or other medical problems. The incidence also increases when children are medicated with hypnotics, sedatives, or anticonvulsants. While not all children who snore have sleep apnea, there is recent literature that raises concerns that snoring without apnea has neurobehavioral consequences. (See Chapter 17.) Obstructive sleep apnea should be suspected whenever a child presents with nightly snoring, witnessed apnea, labored breathing, frequent nighttime arousals, failure to thrive, oxygen desaturations, life-threatening events, behavior abnormalities, obesity, or craniofacial abnormalities. Upper airway resistance syndrome is characterized by the presence of daytime fatigue or sleepiness in the presence of a normal polysomnogram and oxygen saturations. Symptoms are similar to obstructive sleep apnea, including change in appetite, poor performance in school, and problems with behavior.
CHAPTER 18

B. Central Sleep Apnea

Central apneas are common in infants and children. They are considered significant if longer than 20 seconds or associated with bradycardia or desaturations. Clinical significance is uncertain, but may be relevant if they occur frequently or gas exchange problems exist. Healthy children have been shown to have central apneas lasting 25 seconds without clear consequences. In comparison, central hypoventilation syndrome patients have intact voluntary control of ventilation, but lack automatic control. During sleep, they will hypoventilate to the point at which they need ventilatory support that may require treatment with positive airway pressure and a rated tidal volume via tracheostomy. Central sleep apnea may be present with this syndrome, but is not usually noted.

C. Diagnostic Studies

When sleep apnea is suspected, the polysomnogram is the diagnostic test of choice. This test measures sleep state with electroencephalogram leads and electromyography, airflow at the nose, heart rate and rhythm, gas exchange (CO₂ and oxygenation), and leg movements, along with other potential data including esophageal pH, end-tidal CO₂, body position, muscle activity, and other optional additions. Polysomnography allows diagnosis of various forms of apnea, sleep fragmentation, periodic limb movement disorder, or other sleep disorders of children. Overnight oximetry is not a diagnostic test of choice. This test measures sleep state with electroencephalogram leads and electromyography, airflow at the nose, heart rate and rhythm, gas exchange (CO₂ and oxygenation), and leg movements, along with other potential data including esophageal pH, end-tidal CO₂, body position, muscle activity, and other optional additions. Polysomnography allows diagnosis of various forms of apnea, sleep fragmentation, periodic limb movement disorder, or other sleep disorders of children. Overnight oximetry is not an ideal study to diagnose obstructive sleep apnea. While it may identify subjects with severe obstructive sleep apnea, its sensitivity is low. Literature has shown normal oximetry studies in half a population of subjects with polysomnogram-confirmed obstructive sleep apnea.

Treatment

First-line therapy for obstructive sleep apnea in children is adenotonsillectomy, which improves the clinical status for most children with normal craniofacial structure. Even children with craniofacial anomalies or neuromuscular disorders may benefit, although additional treatment with continuous positive airway pressure may be indicated. Down syndrome presents unique challenges: Up to half of these children can still have obstructive sleep apnea despite adenotonsillectomy. Treatment of young or developmentally delayed children with apnea also presents several challenges. (See Chapter 17 for additional discussion.)

Because the differential diagnosis of sleepiness is quite varied among children, pediatric sleep disorder centers are the referral of choice for testing and initiation of therapy.

APPARENT LIFE-THREATENING EVENTS IN INFANCY

General Considerations

Apparent life-threatening events (ALTEs) are characterized as being frightening to the observer and commonly include some combination of apnea, color change (usually cyanosis or pallor), a marked change in muscle tone (usually extreme limping), choking, or gagging. The observer sometimes fears the infant has died. The most frequent problems associated with an ALTE are gastrointestinal (~50%), neurologic (30%), respiratory (20%), cardiovascular (5%), metabolic and endocrine (<5%), or diverse other problems, including child abuse. Up to 50% of ALTEs remain unexplained and are referred to as apnea of infancy. The relationship between ALTE and future risk of sudden infant death syndrome (SIDS) is not clear. The term apparent life-threatening event replaced “near-miss SIDS” in order to distance the event from a direct association with SIDS. Literature has reported an increased risk when extreme cardiopulmonary events were present at the time of the ALTE. Fewer than 10% of SIDS victims have had a prior history of ALTE.

The mechanism for ALTEs is unknown, but because they do not occur after infancy, immaturity is felt to play a major role. Indeed, classic studies on the nervous system, reflexes, and responses to apnea or hypoxia during sleep show profound cardiovascular compromise in infants during stimulation of the immature autonomic nervous system; adults would not be affected.

The following section describes an approach to the patient who has undergone an ALTE, taking note of the very broad diagnostic differential and uncertainties in both evaluation and treatment.

Clinical Findings & Differential Diagnosis

A. History and Physical Examination

Table 18–4 classifies disorders associated with ALTEs. A careful history is often the most helpful part of the evaluation. It is useful to determine whether the infant has been chronically ill or essentially well. A history of several days of poor feeding, temperature instability, or respiratory or gastrointestinal symptoms suggests an infectious process. Reports of “struggling to breathe” or “trying to breathe” imply airway obstruction. Association of the episodes with feeding implies discoordinated swallowing, gastroesophageal reflux, or airway obstruction. Episodes that typically follow crying may be related to breath-holding. Association of

episodes with sleeping may also suggest gastroesophageal reflux, apnea of infancy, or sleep-disordered breathing. Attempts should be made to determine the duration of the episode, but this is often difficult. It is helpful to role-play the episode with the family. Details regarding the measures taken to resuscitate the infant and the infant’s recovery from the episode are often useful in determining severity.

The physical examination provides further direction in pursuing the diagnosis. Fever or hypothermia suggests infection. An altered state of consciousness implies a postictal state or drug overdose. Respiratory distress implies cardiac or pulmonary lesions.

Apneic episodes have been linked to child abuse in several ways. Head injury following nonaccidental trauma may be first brought to medical attention because of apnea. Other signs of abuse are usually immediately apparent in such cases. Drug overdose, either accidental or intentional, may also present with apnea. Several series document that apneic episodes may be falsely reported by parents seeking attention (ie, Münchhausen syndrome by proxy). Parents may physically interfere with a child’s respiratory efforts, in which case pinch marks on the nares are sometimes found.

B. Laboratory Findings

Most patients are hospitalized for observation in order to reduce stress on the family and allow prompt completion of the evaluation. Laboratory evaluation includes a complete blood count for evidence of infection. Serum electrolytes are usually obtained. Elevations in serum bicarbonate suggest chronic hyperventilation, whereas decreases suggest acute acidosis, perhaps due to hypoxia during the episode. Chronic acidosis suggests an inherited metabolic disorder. Arterial blood gas studies provide an initial assessment of oxygenation and acid-base status, and low PaO2 or elevated PacO2 (or both) implies cardiorespiratory disease. A significant base deficit suggests that the episode was accompanied by hypoxia or circulatory impairment. Oxygen saturation measurements in the hospital assess oxygenation status during different activities and are more comprehensive than a single blood gas sample.

Because apnea has been associated with respiratory infections, diagnostic studies for RSV and other viruses, pertussis, and Chlamydia may help with diagnosis. Apnea occurring with infection often precedes other physical findings.

C. Imaging

The chest radiograph is examined for infiltrates suggesting acute infection or chronic aspiration and for cardiac size as a clue to intrinsic cardiac disease. If the episode might have involved airway obstruction, the airway should be examined either directly, by fiberoptic bronchoscopy, or radiographically, by CT or barium swallow. Barium swallow is a useful tool to rule out the possibility of anatomic abnormalities such as vascular ring and tracheoesophageal fistula. This study may also demonstrate reflux and aspiration. If reflux is suspected, it should be documented by esophageal pH monitoring coupled with respiratory pattern recording. Most infants with reflux and apnea can be given medical antireflux treatment. Infants with reflux and repeated episodes of apnea may benefit from a surgical antireflux procedure.

D. Polysomnography and Other Studies

ALTEs occur in the same age group as infants who die of sudden death (2–4 months is the peak age). Sleep-disordered breathing has been implicated as a possible cause of ALTEs and perhaps sudden death. Depending on the discretion of the clinician in appropriate scenarios, polysomnograms can be useful to determine abnormalities of cardiorespiratory function, sleep state, oxygen saturation, CO2 retention, and seizure activity. They can be used in conjunction with pH monitoring to determine the contribution of reflux to apnea. Esophageal pressure manometry can be useful to detect subtle changes in respiratory effort related to partial obstructive breathing (hypopnea). Infants may be at more risk of adverse events from sleep-disordered breathing due to their immature nervous system.

There are several neurologic causes of ALTEs. Apnea as the sole manifestation of a seizure disorder is unusual but may occur. In cases of repeated episodes, 24-hour electroencephalographic monitoring may be helpful in detecting a

seizure disorder. Leigh disease, a brainstem disorder characterized pathologically by neuronal dropout, may present with apneic episodes.

**Treatment**

Therapy is directed at the underlying cause if one is found. After blood cultures are taken, antibiotics should be given to infants who appear toxic. Seizure disorders are treated with anticonvulsants. Gastroesophageal reflux should be treated, but may not prevent future episodes of ALTE. Vascular rings and pulmonary slings must be corrected surgically because of severe morbidity and high mortality rates when untreated.

The approach to care of infants with ALTEs where no definable cause can be ascertained is controversial. Home monitoring has been used in the past as treatment, but the efficacy of monitoring has not been demonstrated in controlled trials. The rationale for use of monitors is that infants at risk for subsequent severe episodes can be identified. With over 20 years of home monitoring, the sudden infant death rate did not change due to this intervention. Although monitors can detect apnea or bradycardia, they do not predict which children will have future ALTEs. Parents should be taught cardiopulmonary resuscitation prior to discharge. They should also be aware of the possibility of frequent false alarms. It must be noted that many parents cannot handle the stress associated with having a monitor in the home.

The decision to monitor these infants involves the participation of the family. Infants with severe initial episodes or repeated severe episodes are now thought to be at significantly increased risk and should probably be monitored in the home. Episodes in these children are so severe that the parents want to know the infant’s condition at all times. The decision to discontinue monitoring is usually based on the infant’s ability to go several months without triggering the alarm.

Oxygen has been used as therapy for ALTEs for several reasons. First, it reduces periodic breathing of infancy, an immature pattern of breathing that can cause some degree of oxygen desaturation. Second, infants have small chest capacities with increased chest wall compliance that reduces lung volume. Oxygen can increase the baseline saturation, reducing the severity of desaturation with short apneas. Respiratory stimulants such as caffeine and aminophylline have been used in specific cases of central apnea or periodic breathing.

---

**SUDDEN INFANT DEATH SYNDROME**

**General Considerations**

SIDS is defined as the sudden death of an infant younger than age 1 year that remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history. The postmortem examination is an important feature of the definition because approximately 20% of cases of sudden death can be explained by autopsy findings. The incidence of SIDS in the United States has declined to less than 1 in 1000 live births. The part of the decline that has occurred since 1994 is likely due to alterations of risk factors (see following discussion).

**Epidemiology & Pathogenesis**

Epidemiologic and pathologic data constitute most of what is known about SIDS. The number of deaths peaks between ages 2 and 4 months, and most deaths occur in infants a few weeks to 6 months of age. Most deaths occur between midnight and 8 AM, while the infant and often the caregiver are sleeping. In fact, the only unifying features of all SIDS cases are age and sleep. Previous studies showed a peak in SIDS during the respiratory virus season, but the association becomes weaker when the data are controlled for risk factors such as tobacco exposure. SIDS is more common among ethnic and racial minorities and socioeconomically disadvantaged populations. Racial disparity in the prevalence of prone positioning may also be contributing to the continued disparity in SIDS rates between black and white infants.

There is a 3:2 male predominance in most series. Other risk factors include low birth weight, teenage or drug-addicted mothers, maternal smoking, and a family history of SIDS. Most of these risk factors are associated with a two- to threefold elevation of incidence but are not specific enough to be useful in predicting which infants will die unexpectedly. Recent immunization is not a risk factor.

The most consistent pathologic findings are intrathoracic petechiae and mild inflammation and congestion of the respiratory tract. Subtler pathologic findings include brainstem gliosis, extramedullary hematopoiesis, and increases in periadrenal brown fat. These latter findings suggest that infants who succumb to SIDS have had intermittent or chronic hypoxia before death.

The mechanism or mechanisms of death in SIDS are unknown. For example, it is unknown whether the initiating event at the time of death is cessation of breathing, cardiac arrhythmia, or asystole. Hypotheses have included upper airway obstruction, catecholamine excess, and increased fetal hemoglobin. However, maldevelopment or delay in maturation of the brainstem, which is responsible for arousal, remains the predominant theory. It has been recognized that some infants who presented with apneic episodes subsequently died from SIDS; however, study of these infants and

---

prospective studies of large numbers of newborns have indicated that most infants with apnea do not die from SIDS and that most infants with SIDS have no identifiable episodes of apnea. The American Academy of Pediatrics has recommended that infant home monitoring not be used as a strategy to prevent SIDS, but may be useful in some infants who have had an ALTE (see section on Apparent Life-Threatening Events, earlier).

A history of mild symptoms of upper respiratory infection before death is not uncommon, and SIDS victims are sometimes seen by physicians a day or so before death. When infants are discovered blue, cold, and motionless by parents or caregivers, they are most commonly taken to the emergency department, where resuscitation usually fails. Families must then be supported following the death. The National SIDS Resource Center (http://www.sidscenter.org) provides information about psychosocial support groups and counseling for families of SIDS victims. The postmortem examination is essential for the diagnosis of SIDS and may help the family by excluding other possible causes of death. A death scene investigation is also important in determining the cause of sudden unexpected deaths in infancy.

### Prevention

Since 1990, SIDS rates have declined more than 60% worldwide. Population studies in New Zealand and Europe identified risk factors, which when changed had a major effect on the incidence of SIDS. Since 1994 the American Academy of Pediatrics’ “Back-to-Sleep” campaign has promoted education about SIDS risk factors in the United States. Modifiable risk factors include sleeping position, bottle feeding, maternal smoking, and infant overheating; sleeping position and smoke exposure may have the largest influence. The prone sleep position could contribute to SIDS through decreased arousal during sleep or during hypoxia, rebreathing of exhaled gases, or effects on the immature autonomic nervous system. The side position, often used in hospitals and then mimicked at home, also shows increased risk of SIDS compared with the supine position. Maternal smoking, especially prenatal maternal smoking, increases the risk of SIDS. Investigations of tobacco effects on the autonomic nervous system of the developing fetus, pulmonary growth and function of the newborn, or its combination with viral infection all point to differences in SIDS compared with control subjects. Although the mechanism is not known, recent literature review has shown a reduced risk of SIDS associated with pacifier use. While beneficial for many reasons, breast feeding is debated regarding decreasing SIDS risk.

The health care provider is instrumental in parental education regarding the modifiable risk factors for SIDS (Table 18–5). Education includes promotion of the supine sleeping position, firm sleep surface, pacifier use at nap or bedtime, avoidance of overheating, and smoking cessation; and identification of child care settings, as many parents rely on others to watch their children, where the importance of infant sleep position may not be recognized. Hospitals should set an example by placing infants in the supine position. With education, the mortality rate may continue to decline.

### MediaStinum

#### MediaStinal Masses

**General Considerations**

Children with mediastinal masses may present because of symptoms produced by pressure on the esophagus, airways, nerves, or vessels within the mediastinum, or the masses may be discovered on a routine chest radiograph. Once the mass is identified, localization to one of four mediastinal compartments aids in the differential diagnosis. The superior mediastinum is the area above the pericardium that is bordered...
inferiorly by an imaginary line from the manubrium to the fourth thoracic vertebra. The anterior mediastinum is bordered by the sternum anteriorly and the pericardium posteriorly, and the posterior mediastinum is defined by the pericardium and diaphragm anteriorly and the lower eight thoracic vertebrae posteriorly. The middle mediastinum is surrounded by these three compartments.

Clinical Findings
A. Symptoms and Signs
Respiratory symptoms, when present, are due to pressure on an airway (cough or wheezing) or an infection (unresolving pneumonia in one area of lung). Hemoptysis can also occur but is an unusual presenting symptom. Dysphagia may occur secondary to compression of the esophagus. Pressure on the recurrent laryngeal nerve can cause hoarseness due to paralysis of the left vocal cord. Superior vena caval obstruction can lead to dilation of neck vessels and other signs and symptoms of obstruction of venous return from the upper part of the body (superior mediastinal syndrome).

B. Laboratory Findings and Imaging
The mass is initially defined by frontal and lateral chest radiographs together with thoracic CT scans and perhaps MRI. A barium swallow may also help define the extent of a mass. Other studies that may be required include angiography (to define the blood supply to large tumors), electrocardiography, echocardiography, ultrasound of the thorax, fungal and mycobacterial skin tests, and urinary catecholamine assays. MRI or myelography may be necessary in children suspected of having a neurogenic tumor in the posterior mediastinum.

Differential Diagnosis
The differential diagnosis of mediastinal masses is determined by their location. Within the superior mediastinum, one may find cystic hygromas, vascular or neurogenic tumors, thymic masses, teratomas, intrathoracic thyroid tissue, and esophageal lesions. A mediastinal abscess may also be found in this region. Within the anterior mediastinum, thymic tissue (thymomas, hyperplasia, and cysts) and teratomas, vascular tumors, and lymphatic tissue (lymphomas or reactive lymphadenopathy) give rise to masses. An intrathoracic thyroid and a pleuropericardial cyst may also be found in this region. Within the middle mediastinum one may again find lymphomas and hypertrophic lymph nodes, granulomas, bronchogenic or enterogenous cysts, metastases, and pericardial cysts. Abnormalities of the great vessels and aortic aneurysms may also present as masses in this compartment. Within the posterior mediastinum, neurogenic tumors, enterogenous cysts, thoracic meningoceles, or aortic aneurysms may be present.

In some series, more than 50% of mediastinal tumors occur in the posterior mediastinum and are mainly neurogenic tumors or enterogenous cysts. Most neurogenic tumors in children younger than age 4 years are malignant (neuroblastoma or neuroangiblastoma), whereas a benign ganglioneuroma is the most common histologic type in older children. In the middle and anterior mediastinum, tumors of lymphatic origin (lymphomas) are the primary concern. Bulky anterior mediastinal tumors that compress the trachea and the great vessels can lead to a superior mediastinal syndrome, which presents a diagnostic problem because of anesthesia hazards. Definitive diagnosis in most instances relies on surgery to obtain the mass or a part of the mass for histologic examination. In cases of lymphoma, the scalene nodes may also contain tumor, and a biopsy should be performed in an attempt to establish a diagnosis.

Treatment & Prognosis
The appropriate therapy and the response to therapy depend on the cause of the mediastinal mass.

Eight in 1000 infants are born with a congenital heart defect. Acquired heart diseases such as Kawasaki disease, myocarditis, and rheumatic heart disease also cause significant morbidity and mortality in children. Advances in medical and surgical care now allow more than 90% of children with congenital heart defects to enter adulthood. It is therefore important that current pediatric cardiac care include not only the diagnosis and treatment of congenital heart disease but also the prevention of risk factors for adult cardiovascular disease—obesity, smoking and hyperlipidemia. Subspecialty clinics addressing the needs of adults with repaired or palliated congenital heart disease are needed to assess and advise patients regarding such adult issues as the impact of pregnancy, the risks of anticoagulation during pregnancy, and appropriate adult career choices.

### DIAGNOSTIC EVALUATION

The presence of a heart murmur suggests the possibility of heart disease. Murmurs, however, may be functional or innocent, and not all serious cardiovascular disorders are accompanied by an easily detectable murmur.

### HISTORY

Most congenital defects lead either to decreased pulmonary blood flow or increased pulmonary blood flow with pulmonary congestion. Symptoms vary according to the alteration in pulmonary blood flow (Table 19–1). The presence of other cardiovascular symptoms such as palpitations and chest pain should also be determined by history in the older child, paying particular attention to the timing (at rest or activity-related), onset, and termination (gradual versus sudden), and precipitating and relieving factors.

### PHYSICAL EXAMINATION

#### General

The examination should begin with a visual assessment of skin perfusion and skin color. Heart rate, respiratory rate, blood pressure (in all four extremities), and oxygen saturation are required. Many congenital cardiac defects occur as part of a genetic syndrome (Table 19–2) and the complete assessment includes an evaluation for dysmorphic features that may be clues to the associated cardiac defect.
## Cardiovascular Examination

### A. Inspection and Palpation

Chest conformation should be noted in the supine position. A precordial bulge indicates cardiomegaly. Palpation may reveal increased precordial activity, right ventricular lift, or left-sided heave; a diffuse point of maximal impulse; or a precordial thrill caused by a grade IV/VI murmur. The thrill of aortic stenosis is found in the suprasternal notch. In patients with severe pulmonary hypertension, a palpable pulmonary closure (P$_2$) is frequently noted at the upper left sternal border.

### B. Auscultation

#### 1. Heart sounds—

The first heart sound (S$_1$) is the sound of atrioventricular (AV) valve closure. It is best heard at the lower left sternal border and is usually medium-pitched. Although S$_1$ has multiple components only one of these (M$_1$) is usually audible.

The second heart sound (S$_2$) is the sound of semilunar valve closure. It is best heard at the upper left sternal border. S$_2$ has two component sounds, A$_2$ and P$_2$ (aortic and pulmonic valve closure). Splitting of S$_2$ varies with respiration, widening with inspiration and narrowing with expiration. Abnormal splitting of S$_2$ may be an indication of cardiac disease (Table 19–3).

The third heart sound (S$_3$) is the sound of rapid left ventricular filling. It occurs in early diastole, after S$_2$, and is medium-to low-pitched. In healthy children, S$_3$ diminishes or disappears when going from supine to sitting or standing. A persistent S$_3$ is often heard in the presence of a dilated left ventricle (LV) caused by cardiomyopathy or a large left-to-right shunt. The fourth heart sound (S$_4$) is associated with atrial contraction and increased atrial pressure and has a low pitch similar to that of S$_1$. It occurs just prior to S$_1$ and is not normally audible. It is heard in the presence of atrial contraction into a noncompliant ventricle as in hypertrophic or restrictive cardiomyopathy or hypertrophied LV from other causes.

Ejection clicks are usually related to dilated great vessels or valve abnormalities. They can be heard throughout ventricular systole and are classified as early, mid, or late. Early ejection clicks at the mid left sternal border are from the pulmonic valve. Aortic clicks are typically best heard at the apex. In contrast to aortic clicks, pulmonic clicks vary with respiration, becoming louder during inspiration. A mid to late ejection click at the apex is most typically caused by mitral valve prolapse.

#### 2. Murmurs—

A heart murmur is the most common cardiovascular finding leading to a cardiology referral. Innocent or functional heart murmurs are common, and 40–45% of children have an innocent murmur at some time during childhood.

**a. Characteristics—**All murmurs should be described based on the following characteristics:

1. **Location and radiation**—Where the murmur is best heard and where the sound extends.
2. **Relationship to cardiac cycle and duration**—Systolic ejection (immediately following S$_1$ with a crescendo/decrescendo change in intensity), pansystolic (occurring through-}

</table>
out most of systole and of constant intensity), diastolic, and continuous. The timing of the murmur provides valuable clues as to underlying pathology (Table 19–4).

(3) Intensity—Grade I describes a soft murmur heard with difficulty; grade II, soft but easily heard; grade III, loud but without a thrill; grade IV, loud and associated with a precordial thrill; grade V, loud, with thrill, and audible with the edge of the stethoscope; grade VI, very loud and audible with the stethoscope off the chest.

(4) Quality—Harsh, musical, or rough; high, medium, or low in pitch.

(5) Variation with position—Audible when the patient is supine, sitting, standing, or squatting.

**B. INNOCENT MURMURS**—The six most common innocent murmurs of childhood are:

(1) Newborn murmur—Heard in the first few days of life, this murmur is at the lower left sternal border, without significant radiation. It has a soft, short, vibratory grade I–II/VI quality that often subsides when mild pressure is applied to the abdomen. It usually disappears by age 2–3 weeks.

(2) Peripheral arterial pulmonary stenosis—This murmur, often heard in newborns, is caused by the normal branching of the pulmonary artery. It is heard with equal intensity at the upper left sternal border, at the back, and in both axillae. It is a soft, short, high-pitched, grade I–II/VI systolic ejection murmur and usually disappears by age 2. This murmur must be differentiated from true peripheral pulmonary stenosis (Williams syndrome, Alagille syndrome, or rubella syndrome), coarctation of the aorta, and valvular pulmonary stenosis.

(3) Still murmur—This is the most common innocent murmur of early childhood. It is typically heard between 2 and 7 years of age. It is loudest midway between the apex and the lower left sternal border. Still murmur is a musical or vibratory, short, high-pitched, grade I–III early systolic murmur. It is loudest when the patient is supine. It diminishes or disappears with inspiration or when the patient is sitting. The Still murmur is louder in patients with fever, anemia, or sinus tachycardia from any reason.

(4) Pulmonary ejection murmur—This is the most common innocent murmur in older children and adults. It is heard from age 3 years onward. It is usually a soft systolic ejection murmur, grade I–II in intensity at the upper left sternal border. The murmur is louder when the patient is supine or when cardiac output is increased. The pulmonary ejection murmur must be differentiated from murmurs of pulmonary stenosis, coarctation of the aorta, atrial septal defect (ASD), and peripheral pulmonary artery stenosis.

(5) Venous hum—A venous hum is usually heard after age 2 years. It is located in the infraclavicular area on the right. It is a continuous musical hum of grade I–III intensity and may be accentuated in diastole and with inspiration. It is best heard in the sitting position. Turning the child’s neck, placing the child supine, and compressing the jugular vein obliterates the venous hum. Venous hum is caused by turbulence at the confluence of the subclavian and jugular veins.

(6) Innominate or carotid bruit—This murmur is more common in the older child and adolescent. It is heard in the right supraclavicular area. It is a long systolic ejection murmur, somewhat harsh and of grade II–III intensity. The bruit can be accentuated by light pressure on the carotid artery and must be differentiated from all types of aortic stenosis.

When functional murmurs are found in a child, the physician should assure the parents that these are normal heart sounds of the developing child and that they do not represent heart disease.

**Extracardiac Examination**

**A. Arterial Pulse Rate and Rhythm**

Cardiac rate and rhythm vary greatly during infancy and childhood, so multiple determinations should be made. This is particularly important for infants (Table 19–5) whose heart rate varies with activity. The rhythm may be regular or there may be a phasic variation with respiration (sinus arrhythmia), which is normal.

**B. Arterial Pulse Quality and Amplitude**

The pulses of the upper and lower extremities should be compared. A bounding pulse is characteristic of run-off lesions, including patent ductus arteriosus (PDA), aortic regurgitation, arteriovenous malformation, or any condition
with a low diastolic pressure (fever, anemia, or septic shock). Narrow or thready pulses occur in patients with conditions reducing cardiac output such as cardiomyopathy, myocarditis, pericardial tamponade, or severe aortic stenosis. A reduction in pulse amplitude or blood pressure (> 10 mm Hg) with inspiration is referred to as pulsus paradoxus and is a telltale sign of pericardial tamponade. The femoral pulse should be palpable and equal in amplitude and simultaneous with the brachial pulse. A femoral pulse that is absent or weak, or that is delayed in comparison with the brachial pulse, suggests coarctation of the aorta.

C. Arterial Blood Pressure
Blood pressures should be obtained in the upper and lower extremities. Systolic pressure in the lower extremities should be greater than or equal to that in the upper extremities. The cuff must cover the same relative area of the arm and leg. Measurements should be repeated several times.

D. Cyanosis of the Extremities
Cyanosis results from an increased concentration (> 4–5 g/dL) of reduced hemoglobin in the blood. Bluish skin color is usually, but not always, a sign. Visible cyanosis accompanies low cardiac output, hypothermia, and systemic venous congestion, even in the presence of adequate oxygenation. Cyanosis should be judged only by the color of the mucous membranes (lips). Bluish discoloration around the mouth (acrocyanosis) is a feature of skin that has not been exposed to sun, and it does not correlate with cyanosis.

E. Clubbing of the Fingers and Toes
Clubbing is often associated with severe cyanotic congenital heart disease. It usually appears after age 1 year. Hypoxemia with cyanosis is the most common cause, but clubbing also occurs in patients with endocarditis, chronic liver disease, inflammatory bowel diseases, chronic pulmonary disease, and lung abscess. Digital clubbing may be a benign genetic variant.

F. Edema
Edema of dependent areas (lower extremities in the older child and the face and sacrum in the younger child) is characteristic of elevated right heart pressure, which may be seen with tricuspid valve pathology or right ventricle (RV) dysfunction (right heart failure) from a variety of causes including LV dysfunction.

G. Abdomen
Hepatomegaly is the cardinal sign of right heart failure in the infant and child. Hepatomegaly may also be seen in the child with pulmonary edema from lesions causing left-to-right shunting or left heart failure. Splenomegaly may be present in patients with long-standing heart failure (HF), and is characteristic of infective endocarditis. Ascites is also a feature of chronic right heart failure. Examination of the abdomen may reveal shifting dullness or a fluid wave.

ELECTROCARDIOGRAPHY
The electrocardiogram (ECG) is essential in the evaluation of the cardiovascular system. The heart rate should first be determined, then the cardiac rhythm (Is the patient in a normal sinus rhythm or other rhythm as evidenced by a P wave with a consistent PR interval before every QRS complex?), and then the axis (Are the P and QRS axes normal for patient age?). Once this initial assessment of rate, rhythm, and axis is performed, attention can be directed toward assessment of chamber enlargement and finally to assessment of cardiac intervals and ST segments.

Age-Related Variations
The ECG evolves with age. The rate decreases and intervals increase with age. RV dominance in the newborn changes to LV dominance in the older infant, child, and adult. The normal ECG of the 1-week-old infant is abnormal for a 1-year-old child, and the ECG of a 5-year-old child is abnormal for an adult.

Electrocardiographic Interpretation
Figure 19–1 defines the events recorded by the ECG.

A. Rate
The heart rate varies markedly with age, activity, and state of emotional and physical well-being. In most infants and
younger children, the heart rate ranges from 70–200 beats per minute depending on the above.

**B. Rhythm**

Sinus rhythm should always be present in normal children. In contrast to adults, premature atrial and ventricular contractions are uncommon during childhood.

**C. Axis**

1. **P wave axis**—The P wave is generated from atrial contraction beginning in the high right atrium at the site of the sinus node. The impulse proceeds leftward and inferiorly, thus leading to a positive deflection in all left-sided and inferior leads (II, III, and aVF). The P wave in patients in normal sinus rhythm should be negative in lead aVR.

2. **QRS axis**—The net voltage should be positive in leads I and aVF in children with a normal axis. In the young child, RV dominance may persist, leading to a negative deflection in lead I. Several congenital cardiac lesions are associated with alterations in the normal QRS axis (Table 19–6).

**D. P Wave**

In the pediatric patient, the amplitude of the P wave is normally no greater than 3 mm and the duration no more than 0.08 second. The P wave is best seen in leads II and V1.

**E. PR Interval**

The PR is measured from the beginning of the P wave to the beginning of the QRS complex. It increases with age and with slower rates. The PR interval ranges from a minimum of 0.10 second in infants to a maximum of 0.18 second in older children with slow rates. The PR interval is commonly prolonged in patients who have rheumatic heart disease and by digitalis.

**F. QRS Complex**

This represents ventricular depolarization, and its amplitude and direction of force (axis) reveal the relative size of the
ventricular mass in hypertrophy, hypoplasia, and infarction. Abnormal ventricular conduction (ie, right or left bundle-branch block) is also revealed.

G. QT Interval

This interval is measured from the beginning of the QRS complex to the end of the T wave. The QT duration may be prolonged as a primary condition or secondarily due to drugs or electrolyte imbalances (Table 19–7). The normal QT duration is rate-related and must be corrected using the Bazett formula:

$$QTC = \frac{QT \text{ interval(s)}}{\sqrt{R - R \text{ interval(s)}}}$$

The normal QTc is less than or equal to 0.44 second.

H. ST Segment

This segment, lying between the end of the QRS complex and the beginning of the T wave, is affected by drugs, electrolyte imbalances, or myocardial injury.

I. T Wave

The T wave represents myocardial repolarization and is altered by electrolytes, myocardial hypertrophy, and ischemia.

J. Impression

The ultimate impression of the ECG is derived from a systematic analysis of the features described earlier as compared with expected normal values for the child’s age.

CHEST RADIOGRAPH

Evaluation of the chest radiograph for cardiac disease should focus on (1) position of the heart, (2) position of the abdominal viscera, (3) cardiac size, (4) cardiac configuration, and (5) character of the pulmonary vasculature.

Cardiac position is either levocardia (heart predominantly in the left chest), dextrocardia (heart predominantly in the right chest), or mesocardia (midline heart). The position of the liver and stomach bubble is either in the normal position (abdominal situs solitus), inverted with the stomach bubble on the right (abdominal situs inversus), or variable with midline liver (abdominal situs ambiguous). The heart appears relatively large in normal newborns and decreases on the chest radiograph with age. The heart size should be less than 50% of the chest diameter in children older than age 1 year. The cardiac configuration on chest radiograph may provide useful diagnostic information, as certain cardiac lesions have a characteristic radiographic appearance (Tables 19–8 and 19–9). The pulmonary vasculature should be assessed. The presence of increased or decreased pulmonary blood flow provides a clue to cardiac diagnosis, particularly in the cyanotic infant (Table 19–10).

The standard posteroanterior and left lateral chest radiographs are used (Figure 19–2).

**Dextrocardia**

Dextrocardia is a radiographic term used when the heart is on the right side of the chest. When dextrocardia occurs with reversal of position of the other important organs of the chest and abdomen (eg, liver, lungs, and spleen), the condition is called situs inversus totalis, and the heart is usually normal. When dextrocardia occurs with the other organs normally located (situs solitus), the heart usually has severe defects.

Rarely, the abdominal organs and lungs are in situs ambiguous. The liver is central and anterior in the upper abdomen, with the stomach pushed posteriorly. Bilateral right-sidedness (asplenia syndrome) or bilateral left-sidedness (polysplenia syndrome) may occur, but in virtually all cases of situs ambiguous, congenital heart disease is present.

### ECHOCARDIOGRAPHY

Echocardiography is a fundamental tool of pediatric cardiology. Using multiple ultrasound modalities (two-dimensional imaging, Doppler, and M-mode), cardiac anatomy, blood flow, intracardiac pressures, and ventricular function can be assessed. Echocardiography is based on the physical principles of sound waves. The ultrasound frequencies utilized in cardiac imaging range from 2–10 million cycles/s.

**M-mode** echocardiography uses short bursts of ultrasound sent from a transducer. At acoustic interfaces, sound waves are reflected back to the transducer. The time it takes for the sound wave to return to the transducer is measured and the distance to the interface is calculated. That calculated distance is displayed against time, and a one-dimensional image is constructed that demonstrates cardiac motion. **Two-dimensional imaging** extends this technique by sending a rapid series of ultrasound bursts across a 90-degree sector, which allows construction of a two-dimensional image of the heart. **Doppler ultrasound** measures blood flow. The ultrasound transducer sends out a known frequency of sound which reflects off moving red blood cells. The transducer receives the reflected frequency and compares it with the transmitted frequency. The blood flow velocity can be calculated from the measured frequency shift. This information is used to estimate pressure gradients by the simplified Bernoulli equation, in which the pressure gradient is equal to four times the calculated velocity (Pressure gradient = 4(V^2)).

A transthoracic echocardiogram is obtained by placing the transducer on areas of the chest where there is minimal lung interference. At each transducer position, the beam is swept through the heart and a three-dimensional image of the heart is constructed in the interpreter’s mind. Complex intracardiac anatomy and spatial relationships can be described, making possible the accurate diagnosis of simple and complex congenital heart disease. In addition to structural details, Doppler gives information about intracardiac blood flow and pressure gradients. Commonly used Doppler techniques include color flow imaging, pulsed wave, and continuous wave Doppler. Color flow imaging gives general information on the direction and velocity of flow. Pulsed and continuous wave Doppler imaging give more precise measurements of blood velocity. The role of M-mode in the ultrasound examination has decreased as other ultrasound modalities have been developed. M-mode is still used to measure LV end-diastolic and end-systolic dimensions and

permits calculation of the LV shortening fraction, a standard estimate of LV function \((SF = \text{LV end-diastolic volume} - \text{LV systolic volume}/\text{LV end-diastolic volume})\).

A typical transthoracic echocardiogram performed by a skilled sonographer takes about 30 minutes, and patients must be still for the examination. Frequently infants and children cannot cooperate for the examination and sedation may be required.

Although echocardiography is an excellent tool for cardiac examination, there are drawbacks to the technique. Two-dimensional imaging can accurately diagnose intracardiac anatomy, but extracardiac structures such as pulmonary arteries and the aortic arch are more difficult to assess. Doppler imaging measures pressure gradients accurately but does not obtain exactly the same information obtained by cardiac catheterization. The indications for pediatric echocardiography are summarized in the American College of Cardiology/American Heart Association (ACC/AHA) practice guidelines published in 2003.

**NUCLEAR CARDIOLOGY**

Nuclear imaging is a useful adjunct to cardiopulmonary exercise testing in assessing both fixed and reversible areas of myocardial ischemia. It is valuable in evaluating myocardial perfusion in patients with Kawasaki disease, repaired anomalous left coronary artery or other coronary anomalies, myocardial bridging in the setting of hypertrophic cardiomyopathy, or chest pain in association with ECG changes with exercise.

**MAGNETIC RESONANCE IMAGING**

Magnetic resonance imaging (MRI) is valuable for evaluation and noninvasive follow-up of many congenital heart defects. It is particularly useful in imaging the thoracic vessels, which are difficult to image by transthoracic echocardiogram. Cardiac gated imaging allows dynamic evaluation of structure and blood flow of the heart and great vessels. It is invaluable to diagnose and follow aortic coarctation, to follow the progress of aortic dilation in Marfan syndrome, to quantify regurgitant lesions such as pulmonary insufficiency after repair of tetralogy of Fallot, and to measure ventricular function in patients with inadequate echocardiographic images. Because it allows computer manipulation of the images of heart and great vessels, three-dimensional MRI is an ideal noninvasive way of obtaining accurate reconstructions of the heart. If a cardiac MRI is performed in a child younger than age 8 years, general anesthesia is often required.

**CARDIOPULMONARY STRESS TESTING**

Most children with heart disease are capable of normal activity. Data on cardiac function after exercise are essential to preventing unnecessary restriction of activities. The response to exercise is helpful in determining the need for and the timing of cardiovascular surgery as well as a useful objective outcome measure of the results of medical and surgical interventions.

Bicycle ergometers or treadmills can be used in children as young as age 5 years. The addition of a metabolic cart enables one to assess whether exercise impairment is secondary to cardiac limitation, pulmonary limitation, deconditioning, or lack of effort. Exercise variables include the ECG, blood pressure response to exercise, oxygen saturation, ventilation, maximal oxygen consumption, and peak work load attained. Cardiopulmonary stress testing is routine in children with congenital cardiac lesions to ascertain limitations, develop exercise prescriptions, assess the effect of therapies, and decide on the need for cardiac transplantation. Stress testing is also employed in children with structurally normal hearts to rule out cardiac or pulmonary pathology in children with symptoms during exertion. Significant stress ischemia or dysrhythmias warrant physical restrictions or appropriate therapy. Children with poor performance due to suboptimal conditioning benefit from a planned exercise program.

**ARTERIAL BLOOD GASES**

Quantitating the partial oxygen pressure \((\text{PaO}_2)\) or \(\text{O}_2\) saturation (eg, by pulse oximetry) during the administration of 100% oxygen is the most useful method of distinguishing cyanosis produced primarily by heart disease or by lung disease in sick infants. In cyanotic heart disease, the partial arterial oxygen pressure \((\text{PaO}_2)\) increases very little when 100% oxygen is administered over the values obtained while breathing room air. However, \(\text{PaO}_2\) usually increases very significantly when oxygen is administered to a patient who has lung disease. Table 19–11 illustrates the

Cardiovascular Diseases

responses seen in patients with heart or lung disease during the hyperoxic test. Routine pulse oximetry has been advocated as an adjunct to the current newborn screening evaluation, as it is a simple, cost-effective means of screening for major cardiac defects prior to hospital discharge.

Cardiac Catheterization & Angiocardiography

Cardiac catheterization precisely defines the anatomic and physiologic abnormalities in simple and complex cardiac malformations. Cardiac catheterization may be performed for diagnostic purposes when further anatomic or physiologic data are needed prior to a therapeutic decision or may be performed for therapeutic purposes when the cardiac condition can be palliated or treated in the catheterization laboratory.

Therapeutic Cardiac Catheterization

Therapeutic procedures performed during cardiac catheterization include coil embolization of a PDA, balloon angioplasty with or without stent placement for aortic coarctation or branch pulmonary artery stenoses, balloon atrial septostomy, valvuoplasty of stenotic aortic or pulmonic valves, and placement of ASD and ventricular septal defect (VSD) devices. Cardiac catheterization is also performed to evaluate the effects of pharmaceutical therapy. An example of this use of catheterization is monitoring changes in pulmonary vascular resistance during the administration of nitric oxide or prostacyclin in a child with primary pulmonary hypertension. Electrophysiologic evaluation and ablation of abnormal electrical pathways in children can be performed by qualified personnel in the pediatric catheterization laboratory.

The risks of cardiac catheterization (morbidity and mortality) must be explained to the patient’s family. Although the risks are very low for elective studies in older children (< 0.1%), the risk of major complications in distressed infants is about 2%. Interventional procedures such as balloon valvuoplasty increase these risks further.

Cardiac Catheterization Data

Figure 19–3 shows oxygen saturation (in percent) and pressure (in millimeters of mercury) values obtained at cardiac catheterization from the chambers and great arteries of the heart. These values are within the normal range for a child.

A. Oxygen Content and Saturation; Pulmonary (Qp) and Systemic (Qs) Blood Flow (Cardiac Output)

In most laboratories, left-to-right shunting is determined by changes of blood oxygen content or saturation during sampling through the right side of the heart. A significant increase in oxygen saturation between one right chamber and the other indicates the presence of a left-to-right shunt at the site of the increase. The oxygen saturation of the peripheral arterial blood should always be determined during cardiac catheterization. Normal arterial oxygen saturation is 95–97% at sea level and 92–94% at 5280 feet. Subnormal saturations suggest the presence of a right-to-left shunt, underventilation, or pulmonary disease.

The size of a left-to-right shunt is usually expressed as a ratio of pulmonary to systemic blood flow (Qp/Qs) or as liters per minute as determined by the Fick principle:

\[
\text{Cardiac output (L/min)} = \frac{\text{Oxygen consumption (mL/min)}}{\text{Arteriovenous difference (mL/L)}}
\]

B. Pressures

Pressures should be determined in all chambers and major vessels entered. It is not normal for systolic pressure in the ventricles to exceed systolic pressure in the great arteries, or mean diastolic pressure in the atra to exceed end-diastolic pressure in the ventricles. If a gradient in pressure exists, an obstruction is present, and the severity of the gradient is one criterion for the necessity of operative repair or catheter intervention. An RV systolic pressure of 100 mm Hg and a
pulmonary artery systolic pressure of 20 mm Hg yield a gradient of 80 mm Hg. In this case, the patient would be classified as having severe pulmonary stenosis requiring balloon dilation of the pulmonic valve or surgery if valvuloplasty fails to significantly reduce the gradient.

C. Pulmonary and Systemic Vascular Resistance

The vascular resistance is calculated from the following formula and reported in units or in dynes × cm−5/m2:

\[
\text{Resistance} = \frac{\text{Pressure}}{\text{Flow}}
\]

The pressure drop used to determine pulmonary vascular resistance is calculated by subtracting the mean pulmonary artery wedge or left atrial pressure from the mean pulmonary artery pressure. This pressure drop is divided by pulmonary blood flow per square meter of body surface area. (Pulmonary blood flow is determined by thermodilution or from the Fick principle, as noted earlier.) Similarly, systemic vascular resistance is determined by subtracting the mean central venous pressure from the mean systemic arterial pressure and dividing this pressure drop by systemic blood flow.

Normally, the pulmonary vascular resistance ranges from 1–3 U/m², or from 80–240 dynes × cm−3/m². Systemic vascular resistance ranges from 15–20 U/m², or from 1200–1600 dynes × cm−3/m². If pulmonary resistance is greater than 10 units or the ratio of pulmonary to systemic resistance is greater than 0.5, the child may have pulmonary vascular disease and therefore be inoperable.

PERINATAL & NEONATAL CIRCULATION

At birth, two events occur that affect the cardiovascular and pulmonary system (1) the umbilical cord is clamped, removing the placenta from the maternal circulation; and (2) breathing commences. As a result, marked changes in the circulation occur. During fetal life, the placenta offers low resistance to blood flow. In contrast, the pulmonary arterioles are markedly constricted and offer high resistance to the flow of blood into the lungs. Pulmonary blood flow accounts for only 7–10% of the combined in utero ventricular output.

At birth, pulmonary blood flow dramatically increases with the fall in pulmonary vascular resistance and pressure. The causes of prolonged high pulmonary vascular resistance include physical factors (lack of an adequate air-liquid interface or ventilation), low oxygen tension, and vasoactive mediators such as elevated endothelin peptide levels or leukotrienes. Clamping the cord produces an immediate increase in resistance to flow in the systemic circuit. As breathing commences, the PO₂ of the small pulmonary arterioles increases, causing their constriction to decrease and producing a decrease in pulmonary vascular resistance. Increased oxygen tension, rhythmic lung distention, and production of nitric oxide as well as prostacyclin play major roles in the fall in pulmonary vascular resistance at birth. The pulmonary vascular resistance falls below that of the systemic circuit, resulting in a reversal in direction of blood flow across the ductus arteriosus.

Functional closure of the ductus arteriosus begins shortly after birth. The ductus arteriosus usually remains patent for 3–5 days. During the first hour after birth, a small right-to-left shunt is present (as in the fetus). However, after 1 hour, bidirectional shunting occurs, with the left-to-right direction predominating. In most cases, right-to-left shunting disappears completely by 8 hours. In patients with severe hypoxia (eg, in the syndrome of persistent pulmonary hypertension of the newborn), pulmonary vascular resistance remains high, resulting in a continued right-to-left shunt. Increased PO₂ of the arterial blood causes spasm of the ductus. Although flow through the ductus arteriosus usually is gone by 5 days of life, the vessel does not close anatomically for 7–14 days.

In fetal life, the foramen ovale serves as a one-way valve shunting blood from the inferior vena cava through the right atrium into the left atrium. At birth, because of the changes in the pulmonary and systemic vascular resistance and the increase in the quantity of blood returning from the pulmonary veins to the left atrium, the left atrial pressure rises above that of the right atrium. This functionally closes the flap of the foramen ovale, preventing flow of blood across the septum. The foramen ovale remains probe patent in 10–15% of adults.

Persistent pulmonary hypertension is a clinical syndrome of full-term infants. The neonate develops tachypnea, cyanosis, and pulmonary hypertension during the first 8 hours after delivery. These infants have massive right-to-left ductal or foramen shunting (or both) for 3–7 days because of high pulmonary vascular resistance. Progressive hypoxia and acidosis will cause early death unless the pulmonary resistance can be lowered. Postmortem findings include increased thickness of the pulmonary arteriolar media. Increase alveolar PO₂ with hyperventilation, alkalosis, paralysis, surfactant administration, high-frequency ventilation, and cardiac pressors can usually reverse the resistance. Inhaled nitric oxide selectively dilates pulmonary vasculature, produces a sustained improvement in oxygenation, and has reduced the need for extracorporeal membrane oxygenation.

In the normal newborn, pulmonary vascular resistance and pulmonary arterial pressure continue to fall during the first weeks of life as a result of demuscularization of the pulmonary arterioles. Adult levels of pulmonary resistance and pressure are normally achieved by 4–6 weeks of age. It is
at this time typically that signs of pulmonary overcirculation associated with left-to-right shunts (VSD or atrioventricular septal defect [AVSD]) appear.

HEART FAILURE

Heart failure (HF) is the clinical condition in which the heart fails to meet the circulatory and metabolic needs of the body. The term congestive heart failure is falling out of favor, as some patients with significant cardiac dysfunction have symptoms of exercise intolerance and fatigue without evidence of congestion. Almost all infants who develop HF from congenital heart lesions do so by 6 months of age. Common causes of HF in infants include VSD, PDA, coarctation of the aorta, AV septal defect, large arteriovenous malformations, and chronic atrial tachyarrhythmias. Metabolic, mitochondrial, and neuromuscular disorders with associated cardiomyopathy present at various ages depending on the diagnosis. HF due to acquired conditions such as myocarditis occur at any age. Children with HF may present with irritability, diaphoresis with feeds, fatigue, exercise intolerance, or evidence of pulmonary congestion (see Table 19–1).

Treatment of Heart Failure

The therapy of HF should be directed toward the underlying cause as well as the symptoms. Regardless of the cause, neurohormonal activation occurs early when ventricular systolic dysfunction is present. Plasma catecholamine levels (eg, norepinephrine) increase and cause tachycardia, diaphoresis, and, by activating the renin-angiotensin system, peripheral vasoconstriction and salt and water retention. There is no gold standard diagnostic or therapeutic approach to HF in children. Treatment must be individualized and therapies should be aimed at improving cardiac performance by targeting the three determinants of cardiac performance: (1) preload, (2) afterload, and (3) contractility.

Inpatient Management of Heart Failure

Patients with cardiac decompensation may require hospitalization for initiation or augmentation of HF therapy. Table 19–12 demonstrates intravenous inotropic agents used to augment cardiac output and their relative effect on heart rate, systemic vascular resistance, and cardiac index. The drug used will depend in part on the cause of the HF.

A. Intravenous Inotropic Support

1. Afterload reduction

   a. Milrinone—This selective phosphodiesterase inhibitor increases cyclic adenosine monophosphate, thereby improving the inotropic state of the heart. In addition to a dose-dependent increase in cardiac contractility, milrinone is a systemic and pulmonary vasodilator and thus an effective agent in both right and left ventricular systolic dysfunction. Milrinone reduces the incidence of low cardiac output syndrome following open heart surgery. The usual dosage range is 0.25–0.75 mcg/kg/min.

b. Nitroglycerin—Nitroglycerin functions primarily as a dilator of venous capacitance vessels and causes a reduction of right and left atrial pressure. Systemic blood pressure may also fall, and reflex tachycardia may occur. Nitroglycerin is used to improve coronary blood flow and may be especially useful when cardiac output is reduced because of coronary underperfusion following congenital heart surgery. The usual intravenous dosage range is 1–3 mcg/kg/min.

2. Enhancement of contractility

   a. Dopamine—This naturally occurring catecholamine increases myocardial contractility primarily via cardiac β-adrenergic activation. Dopamine also directly acts on renal dopamine receptors to improve renal perfusion. The usual dose range for HF is 3–10 mcg/kg/min.

SVR, systemic vascular resistance.
2. Use of pulsatile assist devices is limited in children by patient size, availability, and institutional expertise. These devices allow for less invasive hemodynamic support than ECMO. A cannula positioned in the apex of the ventricle removes blood from the ventricle using a battery-operated pump. Blood is then returned to the patient through a separate cannula positioned in the aorta or pulmonary artery, depending on the ventricle being supported. Ventricular assist carries lower risk of bleeding and pump failure than ECMO, but the risk of infection and thrombosis remain.

**Outpatient Management of Heart Failure**

**A. Medications**

1. **Afterload-reducing agents**—Oral afterload-reducing agents improve cardiac output by decreasing systemic vascular resistance. Angiotensin-converting enzyme (ACE) inhibitors (captopril, enalapril, and lisinopril) are first-line therapy in patients with HF requiring long-term treatment. These agents block angiotensin II–mediated systemic vasoconstriction and are particularly useful in children with structurally normal hearts but reduced LV myocardial function (ie, myocarditis or dilated cardiomyopathies). They are also useful in ameliorating mitral and aortic insufficiency and have a role in controlling refractory HF in patients with large left-to-right shunts in whom systemic vascular resistance is elevated.

2. **β-Blockade**—β-Blockers may be useful adjunctive therapy in children with refractory HF already taking ACE inhibitors. Excessive circulating catecholamines are present due to the activation of the sympathetic nervous system by HF. Although beneficial acutely, this compensatory response over time produces myocardial fibrosis, myocyte hypertrophy, and myocyte apoptosis that contribute to the progression of HF. β-Blockers (eg, carvedilol and metoprolol) antagonize this sympathetic activation and may offset these deleterious effects. Side effects of β-blockers are significant and include bradycardia, hypotension, and worsening HF in some patients.

3. **Diuretics**—Diuretic therapy may be necessary in HF to maintain the euvolemic state.

   a. **Furosemide**—This rapid-acting loop diuretic may be given intravenously or orally. It removes large amounts of potassium and chloride from the body, producing hypochloremic metabolic alkalosis when used chronically. Electrolytes should be monitored during long-term therapy.

   b. **Thiazides**—Thiazides are distal tubular diuretics used to complement furosemide in severe cases of HF.

   c. **Spironolactone**—Spironolactone is a potassium-sparing aldosterone inhibitor. It is used frequently in conjunction with furosemide or thiazides for its enhanced diuretic function. Because it spares potassium, supplemental potassium may be avoided. Spironolactone may also be used as a neurohormonal antagonist with potential benefit in HF regardless of its diuretic effect.

4. **Digitalis**—Digitalis is a cardiac glycoside with a positive inotropic effect on the heart and an associated decrease in systemic vascular resistance. The preparation of digitalis used in clinical practice is digoxin. Large studies in adult patients with HF have not demonstrated decreased mortality of HF with digoxin use, but treatment is associated with reduced hospitalization rates for HF exacerbations.

   a. **Dosing**—The routine schedule consists of giving one half of the total digitalizing dose initially, then one quarter of the total digitalizing dose at 6 and 12 hours of therapy (Table 19–13). Twenty-four hours after the last digitalizing dose, maintenance therapy is started. Serum digoxin levels are not routinely monitored unless there are concerns regarding compliance or toxicity.

   b. **Digitalis toxicity**—Any dysrhythmia that occurs during digoxin therapy should be attributed to the drug until proven otherwise. Ventricular bigeminy and first-, second-, or third-degree AV block are characteristic of digoxin toxicity. A trough level should be obtained if digoxin toxicity is suspected.
c. Digitalis poisoning—This acute emergency must be treated without delay. Digoxin poisoning most commonly occurs in toddlers who have taken their parents’ or grandparents’ medications. The child’s stomach should be emptied immediately by gastric lavage even if several hours have passed since ingestion. Patients who have ingested massive amounts of digoxin should receive large doses of activated charcoal. In advanced heart block, atropine or temporary ventricular pacing may be needed. Digoxin immune Fab can be used to reverse potentially life-threatening intoxication. Antiarrhythmic agents may be useful.

5. Fluid restriction—Fluid restriction is rarely used in pediatric cardiology due to the effectiveness of diuretics. Ensuring adequate caloric intake to promote growth is a more important goal in children with HF.

Genetic Basis of Congenital Heart Disease

Congenital heart disease often has a genetic basis. The most common genetic abnormality is a microdeletion in the long arm of chromosome 22 (22q11) associated with DiGeorge syndrome. These children often have conotruncal abnormalities such as truncus arteriosus, tetralogy of Fallot, or double-outlet RV. Intrauterine factors such as maternal diabetes, alcohol consumption, progesterone use, viral infection, and other maternal teratogen exposure are associated with an increased incidence of cardiac malformations. Genetic diagnosis may allow for more accurate prediction of recurrence risk in subsequent pregnancies.

Atrial Septal Defect (Ostium Secundum Variant)

General Considerations

Atrial septal defect (ASD) is an opening in the atrial septum permitting the shunting of blood between the atria. There are three major types: ostium secundum, ostium primum, and sinus venosus. Ostium secundum is the most common type. Ostium primum defect is associated with atrioventricular septal defect. The sinus venosus defect is frequently associated with abnormal pulmonary venous return, as the location of the sinus venosus is intimately related to the right upper pulmonary vein.

Ostium secundum ASD occurs in 10% of patients with congenital heart disease and is two times more common in females than males. The defect is most often sporadic but may be familial. Pulmonary hypertension and growth failure are uncommon complications in infancy and childhood. After the third decade, atrial arrhythmias or pulmonary vascular disease may develop. In the setting of pulmonary vascular disease, left-to-right shunting decreases, and right-to-left shunting becomes the major clinical abnormality (Eisenmenger syndrome).

Clinical Findings

A. Symptoms and Signs

Most infants and children with ASD have no cardiovascular symptoms. With age, some never develop symptoms. Others develop easy fatigability as older children or adults, or rarely, HF. The direction of flow across the ASD is determined by the compliance of the underlying ventricle. Therefore, cyanosis does not occur unless RV dysfunction occurs, usually as a result of pulmonary hypertension that causes reversal of the shunt across the defect.

Peripheral pulses are normal and equal. The heart is usually hyperactive, with an RV heave felt best at the mid to lower left sternal border. S2 at the pulmonary area is widely split and often fixed. The pulmonary component is normal.
in intensity. A grade I–III/VI ejection-type systolic murmur is heard best at the left sternal border in the second intercostal space. This murmur is caused by increased flow across the pulmonic valve, not flow across the ASD. A mid-diastolic murmur is often heard in the fourth intercostal space at the left sternal border. This murmur is caused by increased flow across the tricuspid valve during diastole. The presence of this murmur suggests high flow with a pulmonary-to-systemic blood flow ratio greater than 2:1.

B. Imaging
Radiographs may show cardiac enlargement. The main pulmonary artery may be dilated and pulmonary vascular markings increased in large defects owing to the increased pulmonary blood flow.

C. Electrocardiography
The usual ECG shows right axis deviation. In the right precordial leads, an rsR’ pattern is usually present. In patients with a mutation in the cardiac homeobox gene (NKX2-5), AV heart block may be present.

D. Echocardiography
Echocardiography shows a dilated right atrium and RV. Direct visualization of the ASD by two-dimensional echocardiography, plus demonstration of a left-to-right shunt through the defect by color-flow Doppler, confirms the diagnosis and has eliminated the need for cardiac catheterization prior to surgical or catheter closure of the defect. Assessment of all pulmonary veins should be made to rule out associated anomalous pulmonary venous return.

E. Cardiac Catheterization
Oximetry shows significant increase in oxygen saturation at the atrial level. The pulmonary artery pressure and pulmonary vascular resistance are usually normal. The Qp:Qs may vary from 1.5:1 to 4:1. Cardiac catheterization is rarely needed for diagnostic purposes but transcatheter closure of an ostium secundum ASD is now the preferred method of closure.

Treatment
Surgical or catheterization closure is generally recommended for symptomatic children with a large atrial level defect and associated right heart dilation. In the asymptomatic child with a large hemodynamically significant defect, closure is performed electively at age 1–3 years. Many defects are amenable to nonoperative device closure during cardiac catheterization, but the defect must have adequate tissue rims on all sides on which to anchor the device. The mortality for surgical closure is less than 1%. When closure is performed by age 3 years, late complications of RV dysfunction and dysrhythmias are avoided.

Course & Prognosis
Patients usually tolerate an ASD well in the first two decades of life, and the defect often goes unnoticed until middle or late adulthood. Pulmonary hypertension and reversal of the shunt are rare late complications. Infective endocarditis is uncommon. Spontaneous closure occurs, most frequently in children with a defect less than 4 mm in diameter. Exercise tolerance and oxygen consumption in surgically corrected children are generally normal, and restriction of physical activity is unnecessary.

2. Ventricular Septal Defect

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Holosystolic murmur at lower left sternal border with RV heave.
- Presentation and course depend on size of defect and the pulmonary vascular resistance.
- Clinical features are HF, failure to thrive, and diaphoresis with feeds.
- Left-to-right shunt with normal pulmonary vascular resistance.
- Large defects may cause Eisenmenger syndrome if not repaired early.

General Considerations
Simple ventricular septal defect (VSD) is the most common congenital heart malformation, accounting for about 30% of all congenital heart disease. Defects in the ventricular septum occur both in the membranous portion of the septum (most common) and the muscular portion. VSDs follow one of four courses:

A. Small, Hemodynamically Insignificant Ventricular Septal Defects
Between 80% and 85% of VSDs are small (< 3 mm in diameter) at birth and will close spontaneously. In general, small defects in the muscular interventricular septum will close sooner than those in the membranous septum. In most cases, a small VSD never requires surgical closure. Fifty percent of
small VSDs will close by age 2 years, and 90% by age 6 years. The remaining 10% will close during the school years. Parents should be told at the time of diagnosis and echocardiographic confirmation that all small VSDs will eventually close.

B. Moderate Ventricular Septal Defects

Asymptomatic patients with moderate VSDs (3–5 mm in diameter) account for 3–5% of children with VSDs. In general, these children do not have clear indicators for surgical closure. Historically, in those who had cardiac catheterization, the ratio of pulmonary to systemic blood flow is usually less than 2:1, and serial cardiac catheterizations demonstrate that the shunts get progressively smaller. If there is neither HF nor pulmonary hypertension, these defects can be followed until spontaneous closure.

C. Large Ventricular Septal Defects with Normal Pulmonary Vascular Resistance

These defects are usually 6–10 mm in diameter. Unless they become markedly smaller within a few months after birth, they will require surgery. The timing of surgery depends on the clinical situation. Many infants with large VSDs and normal pulmonary vascular resistance develop HF and failure to thrive by age 3–6 months, and require correction at that time. In all cases, surgery before age 2 years is required to decrease the risk of pulmonary vascular disease.

D. Large Ventricular Septal Defects with Pulmonary Vascular Obstructive Disease

The direction of flow across a VSD is determined by the downstream resistance, explaining why flow is usually left-to-right. In large VSDs, ventricular pressures are equal, causing increased pulmonary artery pressure. In addition, shear stress caused by increased volume in the pulmonary circuit causes increased resistance over time. The vast majority of patients with inoperable pulmonary hypertension develop the condition progressively. The combined data of the multicenter National History Study indicate that almost all cases of irreversible pulmonary hypertension can be prevented by surgical repair of a large VSD before age 2 years.

Clinical Findings

A. Symptoms and Signs

Patients with small or moderate left-to-right shunts usually have no cardiovascular symptoms. Patients with large left-to-right shunts are usually ill in infancy. These infants have frequent respiratory infections and gain weight slowly. Dyspnea, diaphoresis, and fatigue are common. HF can develop as early as 1 to 6 months of age. After the first year, symptoms usually improve, although easy fatigability may persist. Older children may experience exercise intolerance. Over time, in children with persistent large left-to-right shunt, the pulmonary vascular bed undergoes structural changes, leading to increased pulmonary vascular resistance and reversal of the shunt from left-to-right, to right-to-left (Eisenmenger syndrome). Cyanosis will then be present.

1. Small left-to-right shunt—No lifts, heaves, or thrills are present. The first sound at the apex is normal, and the second sound at the pulmonary area is split physiologically. A grade II–IV/VI, medium- to high-pitched, harsh pansystolic murmur is heard best at the left sternal border in the third and fourth intercostal spaces. The murmur radiates over the entire precordium. No diastolic murmurs are heard.

2. Moderate left-to-right shunt—Slight prominence of the precordium with moderate LV heave is evident. A systolic thrill may be palpable at the lower left sternal border between the third and fourth intercostal spaces. The second sound at the pulmonary area is most often split but may be single. A grade III–IV/VI, harsh pansystolic murmur is heard best at the lower left sternal border in the fourth intercostal space. A mitral diastolic flow murmur indicates that the pulmonary blood flow is significantly increased by the large shunt.

3. Large ventricular septal defects with pulmonary hypertension—The precordium is prominent, and the sternum bulges. Both LV and RV heaves are palpable. S₂ is palpable in the pulmonary area. A thrill may be present at the lower left sternal border. S₁ is usually single or narrowly split, with accentuation of the pulmonary component. The murmur ranges from grade I to grade IV/VI and is usually harsh and pansystolic. Occasionally, when the defect is large or ventricular pressures approach equivalency, a murmur is difficult to hear. A diastolic flow murmur may be heard, depending on the size of the shunt.

B. Imaging

In patients with small shunts, the chest radiograph may be normal. Patients with large shunts have significant cardiac enlargement involving both the left and right ventricles and the left atrium. The main pulmonary artery segment may be dilated. The pulmonary vascular markings are increased.

C. Electrocardiography

The ECG is normal in small left-to-right shunts. Left ventricular hypertrophy (LVH) usually occurs in patients with large left-to-right shunts and normal pulmonary vascular resistance. Combined ventricular enlargement occurs in patients with pulmonary hypertension caused by increased flow, increased resistance, or both. Pure RV hypertrophy occurs in patients with pulmonary hypertension secondary to pulmonary vascular obstruction induced by long-standing left-to-right shunt (Eisenmenger syndrome).

D. Echocardiography

Two-dimensional echocardiography can reveal the size of a VSD and pinpoint its anatomic location. Color-flow Dop-
pler allows detection of the smallest VSDs. Multiple defects can be detected by combining two-dimensional and color-flow imaging. Doppler can further evaluate the VSD by estimating the pressure difference between the left and right ventricles. A pressure difference greater than 50 mm Hg confirms the absence of severe pulmonary hypertension.

E. Cardiac Catheterization and Angiocardiography

The ability to describe the VSD anatomy and estimate the pulmonary artery pressures on the basis of the gradient across the VSD, allows for the vast majority of isolated defects to be repaired without cardiac catheterization and angiocardiography. Catheterization is indicated in those patients with increased pulmonary vascular resistance. The pulmonary artery pressure may vary from normal to systemic level (equal to the aortic pressure). Pulmonary artery wedge pressure (a surrogate for direct left atrial pressure) may be normal to increased. Pulmonary vascular resistance varies from normal to markedly increased. Angiocardiographic examination defines the number, size, and location of the defects.

Treatment

A. Medical Management

Patients who develop HF should receive anticongestive measures (see section on Heart Failure, earlier), particularly diuretics and systemic afterload reduction. If the patient does not respond to anticongestive measures, or if he or she shows progressive pulmonary hypertension, surgery is indicated without delay.

B. Surgical Treatment

Patients with cardiomegaly, poor growth, poor exercise tolerance, or other clinical abnormalities who have a significant shunt (> 2:1) without significant pulmonary hypertension typically undergo surgical repair at age 3–6 months. A synthetic or pericardial patch is used for primary closure. The age of elective surgery has decreased and most defects are now closed in infancy. Patients with pulmonary artery pressures equal to systemic pressure undergo surgical repair well before age 2 years to avoid pulmonary vascular disease. In most centers these children have surgery before age 1 year. As a result, Eisenmenger syndrome has been virtually eliminated. In all cases of VSD, the surgical mortality rate is below 2%.

Transcatheter closure of muscular VSDs is now becoming common. Perimembranous VSDs have also been closed in children during catheterization, but an alarmingly high incidence of complete heart block after placement of the occluding device has slowed the acceptance of this approach.

Course & Prognosis

Significant late dysrhythmias are uncommon. Functional exercise capacity and oxygen consumption are usually normal, and physical restrictions are unnecessary. Adults with corrected defects have normal quality of life. With complete VSD closure, antibiotic prophylaxis for bacterial endocarditis can be discontinued 6 months after surgery.

3. Atrioventricular Septal Defect

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Murmur often inaudible in neonates.
- Loud pulmonary component of S2.
- Common in infants with Down syndrome.
- ECG with extreme left axis deviation.

General Considerations

Atrioventricular septal defect (AVSD) results from incomplete fusion of the embryonic endocardial cushions. The endocardial cushions help to form the “crux” of the heart, which includes the lower portion of the atrial septum, the membranous portion of the ventricular septum, and the septal leaflets of the tricuspid and mitral valves. AVSD accounts for about 4% of all congenital heart disease. Sixty percent of children with Down syndrome have congenital heart disease, and of these, 35–40% has AVSD.

AV septal defects are defined as partial or complete. The physiology of the defect is determined by the location of the AV valves. If the valves are located in the midportion of the defect (complete AVSD), both atrial and ventricular components of the septal defect are present and the left- and right-sided AV valves share a common ring or orifice. In the partial form there is a low insertion of the AV valves resulting in primum ASD without a ventricular component. In partial AVSD, there are two separate AV valve orifices and usually a cleft in the left-sided valve.

Partial AVSD behaves like an isolated ASD with variable amounts of regurgitation through the cleft in the left AV valve. The complete form causes large left-to-right shunts at both the ventricular and atrial levels with AV valve regurgitation. It there is increased pulmonary vascular resistance, the shunts may be bidirectional. Bidirectional shunting is more common in Down syndrome or in older children who have not undergone repair.
Clinical Findings

A. Symptoms and Signs

The partial form may produce symptoms similar to ostium secundum ASD. Patients with complete AVSD usually are severely affected. HF often develops in infancy, and recurrent bouts of pneumonia are common.

In the neonate with the complete form, the murmur may be inaudible due to relatively equal systemic and pulmonary vascular resistance (PVR). After 4–6 weeks, as PVR drops, a nonspecific systolic murmur may be heard at the apex and the lower left sternal border.

If severe pulmonary vascular obstructive disease is present, there is usually dominant RV enlargement. $S_2$ is palpable at the pulmonary area and no thrill is felt. A nonspecific short systolic murmur is heard at the lower left sternal border. No diastolic flow murmurs are heard. In severe cases predominant right-to-left shunting causes cyanosis.

B. Imaging

Cardiac enlargement is always present. In the complete form, all four chambers are enlarged. Pulmonary vascular markings are increased. In patients with pulmonary vascular obstructive disease, only the main pulmonary artery segment and its branches are prominent and the peripheral pulmonary vascular markings are usually decreased.

C. Electrocardiography

In all forms of AVSD, there is extreme left axis deviation with a counterclockwise loop in the frontal plane. The ECG is an important diagnostic tool. Only 5% of isolated VSDs have this ECG abnormality. First-degree heart block occurs in over 50% of patients. Right, left, or combined ventricular hypertrophy is present depending on the particular defect and the presence or absence of pulmonary hypertension.

D. Echocardiography

Echocardiography is the diagnostic test of choice. The anatomy can be well visualized by two-dimensional echocardiography. Both AV valves are at the same level, compared with the normal heart in which the tricuspid valve is more apically positioned. The size of the atrial and ventricular components of the defect can be measured. AV valve regurgitation can be detected. The LV outflow tract is elongated (gooseneck appearance), which produces systemic outflow obstruction.

E. Cardiac Catheterization and Angiocardiography

Cardiac catheterization is not routinely used to evaluate AVSD but may be used to assess pulmonary artery pressures in the older infant with Down syndrome, as this patient group is predisposed to early-onset pulmonary hypertension. Increased oxygen saturation in the RV or the right atrium identifies the level of the shunt. Angiocardiography reveals the characteristic gooseneck deformity of the LV outflow tract in the complete form.

Treatment

Spontaneous improvement does not occur. Surgery is always required. In the partial form, surgery carries a low mortality rate (1–2%), but patients require follow-up because of late-occurring LV outflow tract obstruction and mitral valve dysfunction. The complete form carries a higher mortality rate. Complete correction in the first year of life, prior to the onset of irreversible pulmonary hypertension, is obligatory. If possible, primary correction should be performed when the child is well and weighs more than 5 kg. During surgery, transesophageal echocardiography is used to assess the adequacy of repair before discontinuing cardiopulmonary bypass.

PATENT (PERSISTENT) DUCTUS ARTERIOSUS

General Considerations

PDA is the persistence of the normal fetal vessel joining the pulmonary artery to the aorta. It closes spontaneously in normal term infants at 3–5 days of age. PDA accounts for 10% of all congenital heart disease. The incidence of PDA is higher in infants born at altitudes over 10,000 ft. It is twice as common in females as in males. The frequency of PDA in preterm infants weighing less than 1500 g ranges from 20–60%. The defect may occur as an isolated abnormality or with associated lesions, commonly coarctation of the aorta and VSD. It is critical to recognize patients with a PDA, but without readily apparent findings of other associated lesions, who are being kept alive by the patent ductus (eg, a patient with PDA and unsuspected pulmonary atresia).

Clinical Findings

A. Symptoms and Signs

The clinical findings and course depend on the size of the shunt and the degree of pulmonary hypertension.

1. Typical patent ductus arteriosus—Pulses are bounding, and pulse pressure is widened due to diastolic runoff through the ductus. $S_1$ is normal and $S_2$ is usually narrowly split. In large shunts, $S_2$ may have a paradoxical split (ie, $S_2$ closes on inspiration and splits on expiration). Paradoxical
splitting is caused by volume overload of the LV and prolonged ejection of blood from this chamber.

The murmur is characteristic. It is a rough machinery murmur maximal at the second left intercostal space. It begins shortly after S₁, rises to a peak at S₂, and passes through the S₂ into diastole, where it becomes a decrescendo murmur and fades before the S₁. The murmur tends to radiate well to the anterior lung fields but relatively poorly to the posterior lung fields. A diastolic flow murmur is often heard at the apex.

2. Patent ductus arteriosus with increased pulmonary vascular resistance—Flow across the ductus is diminished. S₂ is single and accentuated, and no significant heart murmur is present. The pulses are normal rather than bounding.

B. Imaging

In simple PDA, the radiographic appearance depends on the size of the shunt. If the shunt is small, the heart is not enlarged. If the shunt is large, both left atrial and LV enlargement may be seen. The aorta and the main pulmonary artery segment may be prominent.

C. Electrocardiography

The ECG may be normal or may show LVH, depending on the size of the shunt. In patients with pulmonary hypertension caused by increased blood flow, biventricular hypertrophy usually occurs. In pulmonary vascular obstructive disease, pure right ventricular hypertrophy (RVH) occurs.

D. Echocardiography

Echocardiography provides direct visualization of the ductus and confirms the direction and degree of shunting. High-velocity left-to-right flow argues against abnormally elevated pulmonary vascular resistance, and as pulmonary vascular resistance drops during the neonatal period, higher velocity left-to-right flow argues against abnormally elevated pulmonary vascular resistance.

E. Cardiac Catheterization and Angiocardiography

Children with PDA never require a cardiac catheterization for diagnostic purposes. However, children more than 5 kg with PDA routinely undergo PDA closure in the catheterization laboratory.

Treatment

Treatment is surgical when the PDA is large and the patient is small, except in patients with pulmonary vascular obstructive disease. Patients with large left-to-right shunts require repair by age 1 year to prevent the development of progressive pulmonary vascular obstructive disease. Symptomatic PDA with normal pulmonary artery pressure can be safely coil or device-ocluded in the catheterization laboratory after the child has reached 5 kg.

Patients with nonreactive pulmonary vascular obstruction with resistance greater than 10 Wood units (normal, < 3) and a ratio of pulmonary to systemic resistance greater than 0.7 (normal, < 0.3) despite vasodilator therapy (eg, nitric oxide) should not undergo PDA closure. These patients are made worse by PDA closure because the flow through the ductus maintains cardiac output to the systemic circulation in the presence of high pulmonary vascular resistance.

Symptomatic PDA is common in preterm infants. Indomethacin, a prostaglandin synthesis inhibitor, is often used to close PDA in premature infants. Indomethacin does not close the PDA of full-term infants or children. The success of indomethacin therapy is as high as 80–90% in premature infants with a birth weight greater than 1200 g, but it is less successful in smaller infants. Indomethacin (0.1–0.3 mg/kg orally every 8–24 hours or 0.1–0.3 mg/kg parenterally every 12 hours) can be used if there is adequate renal, hematologic, and hepatic function. Because indomethacin may impair renal function, urine output, BUN, and creatinine should be monitored during therapy. If indomethacin is not effective and the ductus remains hemodynamically significant, surgical ligation should be performed. If the ductus closes substantially so that it is no longer hemodynamically significant, even with some residual flow from left to right, surgery is not needed, and a second course of indomethacin may be used. Recent studies from Europe indicate that ibuprofen may be as effective as indomethacin for medical closure of preterm PDA.

Course & Prognosis

Patients with simple PDA and small-to-moderate shunts usually do well without surgery. However, in the third or fourth decade of life, symptoms of easy fatigability, dyspnea on exertion, and exercise intolerance appear, usually as a consequence of progressive pulmonary hypertension or HF.

Spontaneous closure of a PDA may occur up to age 1 year, especially in preterm infants. After age 1 year, spontaneous closure is rare. Because infective endocarditis is a potential complication, closure is recommended if the defect persists beyond age 1 year.

The prognosis for patients with large shunts or pulmonary hypertension is not as good. Poor growth and development, frequent pneumonias, and HF occur in these children. Patients beyond the newborn period with PDA and large shunts should have transcatheter device closure of their PDA.

RIGHT-SIDED OBSTRUCTIVE LESIONS

1. Pulmonary Valve Stenosis

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- No symptoms in mild or moderate stenosis.
- Cyanosis and a high incidence of right-sided HF in ductal-dependent lesions.
- RV lift with systolic ejection click heard at the third left intercostal space.
- $S_2$ widely split with soft to inaudible $P_2$; grade I–VI systolic ejection murmur, maximal at the pulmonary area.
- Dilated pulmonary artery on chest radiograph.

**General Considerations**

Pulmonic valve stenosis accounts for 10% of all congenital heart disease. In the usual case, the cusps of the pulmonary valve are fused to form a membrane or diaphragm with a hole in the middle from 2–10 mm in diameter. Occasionally, only two cusps are fused, producing a bicuspid pulmonary valve. In more severe cases, secondary infundibular (sub-valve) stenosis occurs. The pulmonary valve annulus is usually small with moderate to marked poststenotic dilation of the main pulmonary arteries.

Obstruction to blood flow across the pulmonary valve causes an increase in RV pressure. Pressures greater than systemic are potentially life-threatening and are associated with critical obstruction. Because of the increased RV strain, severe RVH and eventual RV failure can occur.

When obstruction is severe and the ventricular septum is intact, a right-to-left shunt will often occur at the atrial level through a patent foramen ovale. In neonates with severe obstruction, pulmonary blood flow will shunt through the ductus, making prostaglandin a necessary intervention at the time of birth. Patients with this condition are cyanotic.

**Clinical Findings**

**A. Symptoms and Signs**

Patients with mild or even moderate valvular pulmonary stenosis are acyanotic and asymptomatic. Patients with severe valvular obstruction may develop cyanosis early. Patients with mild to moderate obstruction are usually well developed and well nourished. They are not prone to pulmonary infections. The pulses are normal. The precordium may be prominent, often with palpable RV heave. A systolic thrill is often present in the pulmonary area. In patients with mild to moderate stenosis, a prominent ejection click of pulmonary origin is heard at the third left intercostal space. The click varies with respiration, being more prominent during expiration than inspiration. In severe stenosis, the click tends to merge with $S_1$. $S_2$ varies with the degree of stenosis. In mild pulmonic stenosis, $S_2$ is normal. In moderate pulmonic stenosis, $S_2$ is more widely split and the pulmonary component is softer. In severe pulmonary stenosis, $S_2$ is single because the pulmonary component cannot be heard. A rough systolic ejection murmur is best heard at the second left interspace. It radiates well to the back. With severe pulmonary valve obstruction, the murmur is usually short. No diastolic murmurs are audible.

**B. Imaging**

The heart size is normal. Post-stenotic dilation of the main pulmonary artery and the left pulmonary artery often occurs.

**C. Electrocardiography**

The ECG is usually normal with mild obstruction. RVH is present with moderate to severe pulmonic stenosis. In severe obstruction, RV hypertrophy with an RV strain pattern (deep inversion of the T wave) occurs in the right precordial leads ($V_3R, V_1, V_2$). Right atrial enlargement may be present. Right axis deviation occurs in moderate to severe stenosis.

**D. Echocardiography**

The diagnosis often is made by physical examination, but the echocardiogram supports the diagnosis when the pulmonary valve is unusually thickened with reduced valve leaflet excursion. The transvalvular pressure gradient can be estimated accurately by Doppler, which provides evidence of the RV pressure and can assist in determining the appropriate time to intervene.

**E. Cardiac Catheterization and Angiocardiography**

Pulmonic stenosis is easily diagnosed by physical examination, ECG, and echocardiography. Catheterization is reserved for therapeutic balloon pulmonic valvuloplasty. In severe cases with RV dysfunction, a right-to-left shunt at the atrial level is indicated by a lower left atrial saturation than pulmonary vein saturation. Pulmonary artery pressure is normal. The gradient across the pulmonary valve varies from 10–200 mm Hg. In severe cases, the right atrial pressure is elevated, with a predominant “a” wave. Angiocardiography in the RV shows a thick pulmonary valve with a narrow opening producing a jet of contrast into the pulmonary artery. Infundibular (RV outflow tract) hypertrophy may be present.

**Treatment**

Relief of pulmonic stenosis is recommended for children with RV systolic pressure greater than two thirds of systemic
pressure. Immediate correction is indicated for patients with systemic or suprasystemic RV pressure. Percutaneous balloon valvuloplasty is the procedure of choice. It is as effective as surgery in relieving obstruction and causes less valve insufficiency. Surgery is needed to treat pulmonic valve stenosis when balloon pulmonic valvuloplasty is unsuccessful.

Course & Prognosis

Patients with mild pulmonary stenosis live normal lives. Even those with moderate stenosis are rarely symptomatic. Those with severe valvular obstruction may develop cyanosis in infancy.

After balloon pulmonary valvuloplasty or surgery, most patients have good maximum exercise capacity unless they have significant pulmonary insufficiency (PI). Limitation of physical activity is unwarranted. The quality of life of adults with successfully treated pulmonary stenosis and minimal PI is normal. Patients with PI, a frequent side effect of intervention, may be significantly limited in exercise performance. Severe PI leads to progressive RV dilation and dysfunction, which may precipitate ventricular arrhythmias or right heart failure in adulthood. Patients with severe PI may benefit from replacement of the pulmonic valve.

4. Peripheral (Branch) Pulmonary Artery Stenosis

In peripheral pulmonary stenosis, there are multiple narrowings of the branches of the pulmonary artery at the bifurcation of the main pulmonary artery or in the periphery of the lung. Systolic murmurs may be heard over both lung fields, anteriorly and posteriorly. Mild pulmonary branch stenosis produces a murmur in infancy that resolves by 6 months of age. Severe forms of peripheral pulmonary stenosis persist. The three most common causes of pulmonary artery branch stenosis are Williams syndrome, Alagille syndrome, and congenital rubella. Surgery is often unsuccessful, as stenoses near and in the hilum of the lung are not surgically correctable. Transcatheter balloon angioplasty is currently being used to treat this condition, with moderate success. In some instances, the stenoses improve spontaneously with age.

5. Ebstein Malformation of the Tricuspid Valve

In Ebstein malformation of the tricuspid valve, the septal leaflet of the tricuspid valve is displaced toward the apex of the heart and is attached to the endocardium of the RV rather than at the tricuspid annulus. As a result, the upper portion of the RV is physiologically within the right atrium. This “atrialized” portion of the RV is thin-walled and does not contribute to RV output. The portion of the ventricle below the displaced tricuspid valve is diminished in volume and represents the functioning RV.

Clinical Findings

A. Symptoms and Signs

The clinical picture of Ebstein malformation varies with the degree of displacement of the tricuspid valve. In the most extreme form, the septal leaflet is markedly displaced into the RV outflow tract, causing obstruction of antegrade flow into the pulmonary artery. The degree of tricuspid insufficiency may be so severe that forward flow out the RV outflow tract is further diminished leading to cyanosis. At the opposite extreme, symptoms may not develop until adulthood when tachyarrhythmias associated with right atrial dilation or associated reentrant electrical pathway occur. These older patients typically have less displacement of the septal leaflet of the tricuspid valve.

B. Imaging

The chest radiograph usually shows cardiomegaly with prominence of the right heart border. The extent of cardiomegaly depends on the degree of tricuspid valve insufficiency and the presence and size of the atrial level shunt. Massive cardiomegaly with a “wall-to-wall heart” occurs with severe displacement and a restrictive atrial level defect.
C. Electrocardiography

ECG may be normal but usually shows right atrial enlargement and right bundle-branch block (RBBB). There is an association between Ebstein anomaly and Wolff-Parkinson-White (WPW) syndrome. In these cases a delta wave is present.

D. Echocardiography

Echocardiography is necessary to confirm the diagnosis and may aid in predicting outcome. Degree of displacement, size of the right atrium, and presence of associated atrial level shunt all affect outcome. The size of the atrialized portion of the RV is determined by echocardiography, and in severe cases, the RV can become so enlarged that it encroaches on the LV mass, impeding LV filling.

Course & Prognosis

In cyanotic neonates, prostaglandin E is used to maintain pulmonary blood flow until pulmonary vascular resistance decreases, facilitating antegrade pulmonary artery flow. If the neonate remains significantly cyanotic, surgical intervention is required but the outcome is poor. Intervention in older children or adults has a better outcome.

Surgical repair consists of an annuloplasty to modify the level of the tricuspid orifice and diminish tricuspid insufficiency. The success of the procedure is highly variable. Late arrhythmias are common due to the preexisting atrial dilation. If a significant Ebstein malformation is not treated, atrial tachyarrhythmias frequently begin during adolescence. Postoperative exercise tolerance improves but remains lower than age-related norms.

6. Other Rare Right-Sided Malformations

A. Absence of a Pulmonary Artery

Absence of a pulmonary artery (left or right) may be an isolated malformation or may occur in association with other congenital heart diseases. It occurs occasionally in patients with tetralogy of Fallot.

B. Absence of the Pulmonary Valve

Absence of the pulmonary valve is rare and usually associated with VSD. In about 50% of cases, infundibular pulmonary stenosis is also present (termed tetralogy of Fallot with absent pulmonary valve).

LEFT-SIDED OBSTRICTIVE LESIONS

1. Coarctation of the Aorta

Absent or diminished femoral pulses.
Upper to lower extremity systolic blood pressure gradient of > 20 mm Hg.
Blowing systolic murmur in the back or left axilla.

General Considerations

Coarctation accounts for about 6% of all congenital heart disease. Three times as many males as females are affected. Many affected females have Turner syndrome (45,XO). Coarctation usually occurs in the proximal descending aorta near the takeoff of the left subclavian artery next to the ductus arteriosus. The abdominal aorta is rarely involved. The incidence of associated bicuspid aortic valve with coarctation is 80–85%.

Clinical Findings

A. Symptoms and Signs

The cardinal physical finding is decreased or absent femoral pulses. Infants with severe coarctation have equal upper and lower extremity pulses from birth until the ductus arteriosus closes. This is either because the coarctation is so severe that the ductus supplies blood flow to the descending aorta, or because the coarctation itself is the result of ductal tissue in the aorta sufficient to cause aortic obstruction. Approximately 40% of children with coarctation will present as young infants. Coarctation alone, or in combination with VSD, ASD, or other congenital cardiac anomalies, is the leading cause of HF in the first month of life.

Coarctation presents insidiously in the 60% of children with no symptoms in infancy. Coarctation is usually diagnosed by a pulse discrepancy between the arms and legs on physical examination or by right arm hypertension on blood pressure measurement. The pulses in the legs are diminished or absent. The left subclavian artery is occasionally involved in the coarctation, in which case the left brachial pulse is also weak. The pathognomonic murmur of coarctation is heard in the left axilla and the left back. The murmur is usually systolic but may spill into diastole, as forward flow continues across the narrow coarctation site throughout the cardiac cycle. A systolic ejection murmur is often heard at the aortic area and the lower left sternal border along with an apical ejection click from a bicuspid aortic valve.

B. Imaging

In the older child, radiographs may show a normal-sized heart, or more often some degree of LV enlargement. The
aorta proximal to the coarctation is prominent. The aortic outline may indent at the level of the coarctation. The poststenotic segment is often dilated. This combination of abnormalities results in the “figure 3” sign on chest radiograph. Notching of the ribs caused by marked enlargement of the intercostal collaterals can be seen. In patients with severe coarctation and associated HF, marked cardiac enlargement and pulmonary venous congestion occur.

C. Electrocardiography

ECGs in older children may be normal or may show LVH. ECG usually shows RVH in infants with severe coarctation because the RV has been a “systemic” ventricle during fetal life.

D. Echocardiography

Two-dimensional echocardiography and color-flow Doppler are used to visualize the coarctation directly, and continuous-wave Doppler estimates the degree of obstruction. Diastolic run-off flow is detected by continuous-wave Doppler if the obstruction is severe. In neonates with a PDA, a coarctation cannot be ruled out, as one may develop as the PDA closes. Associated lesions such as a bicuspid aortic valve or mitral abnormalities may suggest the presence of a coarctation. In the face of poor LV systolic function, the gradient across the coarctation will be falsely low, as the LV is unable to generate adequate pressure proximal to the narrowing.

E. Cardiac Catheterization and Angiocardiography

Cardiac catheterization and angiocardiography are rarely performed for diagnosis in infants or children with coarctation, but are used if transcatheter intervention is planned. If completed, these studies demonstrate the anatomy and severity of the coarctation and assess the adequacy of collateral circulation.

Treatment

Infants with coarctation of the aorta and HF may present in extremis secondary to LV dysfunction and low cardiac output. Resuscitative measures include prostaglandin infusion (0.05–0.1 mcg/kg/min) to reopen the ductus arteriosus. End-organ damage distal to the coarctation is not rare, and inotropic support is frequently needed. Once stabilized, the infant should undergo corrective repair. In patients with poor LV function, balloon angioplasty is sometimes performed as a palliative measure. Recent data suggest that balloon angioplasty of the aorta can be the definitive procedure in many patients with good LV function. Surgery also has a high success rate. The main complication of both surgery and balloon angioplasty is recurrent coarctation. Fortunately, this complication is treatable in the catheterization laboratory. In older patients, particularly those of adult size, transcatheter stent placement is effective for recurrent coarctation.

Course & Prognosis

Children who survive the neonatal period without developing HF do well through childhood and adolescence. Fatal complications (eg, hypertensive encephalopathy or intracranial bleeding) are uncommon in childhood. Infective endarteritis is rare before adolescence. Children with coarctation corrected after age 5 years are at increased risk for systemic hypertension and myocardial dysfunction even with successful surgery. Exercise testing is mandatory for these children prior to their participation in athletic activities.

2. Aortic Stenosis

- Harsh systolic ejection murmur at the upper right sternal border.
- Thrill in the carotid arteries.
- Systolic click at the apex.
- Dilation of the ascending aorta on chest radiograph.

General Considerations

Aortic stenosis is defined as obstruction to outflow from the LV at or near the aortic valve producing a systolic pressure gradient of more than 10 mm Hg between the LV and the aorta. Aortic stenosis accounts for approximately 7% of congenital heart disease. There are three anatomic types of congenital aortic stenosis.

A. Valvular Aortic Stenosis (75%)

In critical aortic stenosis presenting in infancy, the aortic valve is usually a unicuspid diaphragm-like structure without well-defined commissures. Preschool- and school-aged children more commonly have bicuspid aortic valve. Teenagers and young adults characteristically have a tricuspid valve with partially fused leaflets. This lesion is more common in males than in females.

B. Subvalvular Aortic Stenosis (23%)

In this type, a membranous or fibrous ring occurs just below the aortic valve that causes obstruction to LV outflow. The aortic valve itself and the anterior leaflet of the mitral valve are often malformed.
C. Supravalvular Aortic Stenosis (2%)

In this type, constriction of the ascending aorta occurs just above the coronary arteries. The condition is often familial, and two different genetic patterns are found, one with abnormal facies and mental retardation (Williams syndrome) and one with normal facies and no developmental delay.

Clinical Findings

A. Symptoms and Signs

Most patients with aortic stenosis have no cardiovascular symptoms. Except in the most severe cases, patients do well until the third to fifth decades of life. Some patients have mild exercise intolerance and fatigability. In a small percentage of patients significant symptoms (i.e., dizziness and syncope) manifest in the first decade. Sudden death is uncommon but may occur in all forms of aortic stenosis with the greatest risk in patients with subvalvular obstruction (similar to hypertrophic cardiomyopathy).

Although isolated valvular aortic stenosis seldom causes symptoms in infancy, severe HF occasionally occurs when critical obstruction is present at birth. Response to medical therapy is poor; therefore, an aggressive approach using interventional catheterization or surgery is required. The physical findings vary depending on the anatomic type of lesion:

1. Valvular aortic stenosis—Patients are well developed and well nourished. Pulses are usually normal and equal throughout. If the stenosis is severe with a gradient greater than 80 mm Hg, the pulses are diminished with a slow upstroke. Cardiac examination reveals an LV thrust at the apex. A systolic thrill at the right base, the suprasternal notch, and over both carotid arteries may accompany moderate disease.

   A prominent aortic ejection click is best heard at the apex. The click corresponds to the opening of the aortic valve. It is separated from S1 by a short but appreciable interval. It does not vary with respiration. S2 at the pulmonary area is normal. A loud, rough, medium- to high-pitched ejection-type systolic murmur is evident. It is loudest at the first and second intercostal spaces, radiating well into the suprasternal notch and along the carotids. The grade of the murmur correlates well with the severity of the stenosis.

2. Discrete membranous subvalvular aortic stenosis—The findings are the same as those of valvular aortic stenosis except for the absence of a click. The murmur and thrill are usually somewhat more intense at the left sternal border in the third and fourth intercostal spaces. A diastolic murmur of aortic insufficiency is commonly heard after age 5 years.

3. Supravalvular aortic stenosis—The thrill and murmur are best heard in the suprasternal notch and along the carotids but are well transmitted over the aortic area and near the mid left sternal border. There may be a difference in pulses and blood pressure between the right and left arms if the narrowing is just distal to the takeoff of the innominate artery, with more prominent pulse and pressure in the right arm (the Coanda effect).

B. Imaging

In most cases the heart is not enlarged. The LV, however, may be slightly prominent. In valvular aortic stenosis, dilation of the ascending aorta is frequently seen.

C. Electrocardiography

Patients with mild aortic stenosis have normal ECGs. Some patients with severe obstruction have LVH and LV strain but even in severe cases, 25% of ECGs are normal. Progressive LVH on serial ECGs indicates a significant obstruction. LV strain is an indication for surgery.

D. Echocardiography

This is a reliable noninvasive technique for the evaluation of all forms of aortic stenosis. Doppler accurately estimates the transvalvular gradient, and the level of obstruction can be confirmed by both two-dimensional echocardiographic images and by the level of flow disturbance revealed by color Doppler.

E. Cardiac Catheterization and Angiocardiography

Left heart catheterization demonstrates the pressure differential between the LV and the aorta and the anatomic level at which the gradient exists. Echocardiography is the standard method for following the severity of aortic valve stenosis, and catheterization is reserved for patients whose resting gradient has reached 60–80 mm Hg and in whom intervention is planned. For those with valvular aortic stenosis, balloon valvuloplasty is usually the first option. In subvalvular or supravalvular aortic stenosis, interventional catheterization is not effective and surgery is required.

Treatment

Percutaneous balloon valvuloplasty is now standard initial treatment. Surgery should be considered in patients with symptoms, a high resting gradient (60–80 mm Hg) despite balloon angioplasty, or coexisting aortic insufficiency. In many cases, the gradient cannot be significantly diminished without producing aortic insufficiency. Patients who develop significant aortic insufficiency require surgical intervention to repair or replace the valve. In the Ross procedure, the patient’s own pulmonic valve is moved to the aortic position, and an RV-to-pulmonary artery conduit is used to replace the pulmonic valve. Discrete subvalvular aortic stenosis is usually surgically repaired at a lesser gradient because continued trauma to the aortic valve by the subvalvular jet may damage the valve and produce aortic insufficiency. Unfortunately, simple resection is followed by recurrence in more than 25% of patients with subvalvular aortic stenosis.
Course & Prognosis

All forms of LV outflow tract obstruction tend to be progressive. Pediatric patients with LV outflow tract obstruction—with the exception of those with critical aortic stenosis of infancy—are usually asymptomatic. Symptoms accompanying severe unoperated obstruction (angina, syncope, or HF) are rare but imply serious disease. Preoperative or postoperative children whose obstruction is mild to moderate have normal oxygen consumption and maximum voluntary working capacity. Children in this category with normal heart size and normal resting and exercising ECGs may safely participate in vigorous physical activity, including nonisometric competitive sports. Children with severe aortic stenosis are predisposed to ventricular dysrhythmias.

3. Mitral Valve Prolapse

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Midsystolic click.
- Late systolic “whooping” or “honking” murmur.
- Typical symptoms include chest pain, palpitations, and dizziness.
- Often overdiagnosed on routine cardiac ultrasound.

General Considerations

In this condition the mitral valve prolapses, moving posteriorly or superiorly into the left atrium during ventricular systole as the mitral valve closes. A midsystolic click occurs at the time of this movement and is the hallmark of this entity. Mitral insufficiency may occur late in systole, causing a short, atypical murmur with variable radiation. Mitral valve prolapse (MVP) occurs in about 2% of thin female adolescents, a minority of whom have concomitant mitral insufficiency. Although MVP is usually an isolated lesion, it can occur in association with Marfan syndrome and Ehlers-Danlos syndrome. These coexisting conditions should be ruled out by clinical examination.

Clinical Findings

A. Symptoms and Signs

Most patients with MVP are asymptomatic. Chest pain, palpitations, and dizziness may be reported, but it is unclear whether these symptoms are more common in affected patients than in the normal population. Chest pain on exertion is rare and should be assessed with cardiopulmonary stress testing. Significant dysrhythmias have been reported, including increased ventricular ectopy and nonsustained ventricular tachycardia. If significant mitral regurgitation is present, atrial arrhythmias may also occur. Standard auscultation technique must be modified to diagnose MVP. Clicks, with or without systolic murmur, are elicited best in the standing position due to the decrease in LV volume. Conversely, maneuvers that increase LV volume, such as squatting or handgrip exercise, will cause delay or obliteration of the click-murmur complex. The systolic click usually is heard at the apex but may be audible at the left sternal border. A systolic murmur after the click implies mitral insufficiency and is much less common than isolated prolapse. The murmur is not holosystolic, in contrast to rheumatic mitral insufficiency.

B. Imaging

Most chest radiographs are normal. They are not indicated in this condition. In the rare case of significant mitral valve insufficiency, the left atrium may be enlarged.

C. Electrocardiography

The ECG may be normal. Diffuse flattening or inversion of T waves may occur in the precordial leads. U waves are sometimes prominent.

D. Echocardiography

Significant posterior systolic movement of the mitral valve leaflets to the atrial side of the mitral annulus is diagnostic. Echocardiography assesses the degree of myxomatous change of the mitral valve and the degree of mitral insufficiency.

E. Other Testing

Invasive procedures are rarely indicated. Holter monitoring or event recorders may be useful in establishing the presence of ventricular dysrhythmias in patients with palpitations.

Treatment & Prognosis

Propranolol may be effective in treatment of coexisting arrhythmias. Prophylaxis for infectious endocarditis is no longer indicated, based on 2007 AHA guidelines.

The natural course of this condition is not well defined. Twenty years of observation indicate that isolated MVP in childhood is usually a benign entity. Surgery for mitral insufficiency is rarely needed.

4. Other Congenital Left Heart Valvular Lesions

A. Congenital Mitral Stenosis

Congenital mitral stenosis is a rare disorder in which the valve leaflets are thickened and fused, producing a diaphragm-like or funnel-like structure with a central opening. When mitral stenosis occurs with other left-sided obstructive lesions, such as subaortic stenosis and coarctation of the aorta, the complex is called Shone syndrome. Most patients develop symptoms early in life with tachypnea, dyspnea, and failure to thrive. Physical examination reveals an accentuated S1 and a loud pulmonary closure sound. No opening snap can be heard. In most cases, a presystolic crescendo murmur is heard at the apex. Occasionally, only a mid-diastolic murmur can be heard. Rarely, no murmur is present. ECG shows right axis deviation, biventricular enlargement, and RVH. Chest radiograph reveals left atrial enlargement and frequently pulmonary venous congestion. Echocardiography shows abnormal mitral valve structures with reduced leaflet excursion and left atrial enlargement. Cardiac catheterization reveals an elevated pulmonary capillary wedge pressure and pulmonary hypertension, owing to the elevated left atrial pressure.

Mitral valve repair or mitral valve replacement with a prosthetic mitral valve may be performed, even in young infants, but is a technically difficult procedure. Mitral valve repair is the preferred surgical option, as valve replacement has a poor outcome in very young children.

B. Cor Triatriatum

Cor triatriatum is a rare abnormality in which the pulmonary veins join at their confluence but the confluence is not completely incorporated into the left atrium. The confluence communicates with the left atrium through an opening of variable size, and may be obstructed. The consequences are similar to those of mitral stenosis. Clinical findings depend on the size of the opening. If the opening is small, symptoms develop early in life. Echocardiography reveals a linear density in the left atrium with a gradient between the pulmonary venous chamber and the true left atrium. Cardiac catheterization may be needed if the diagnosis is in doubt. High pulmonary wedge pressure and low left atrial pressure (with the catheter passed through the foramen ovale into the true left atrium) support the diagnosis. Angiocardiology identifies both the proximal and distal left atria. Surgical repair is always required in the presence of an obstructive membrane, and long-term results are good. Coexisting mitral valve abnormalities may be noted, including a supravalvular mitral ring or a dysplastic mitral valve.

C. Congenital Mitral Regurgitation

Congenital mitral regurgitation is a rare abnormality usually associated with other congenital heart lesions, such as ccTGA, AV septal defect, and anomalous left coronary artery. Isolated congenital mitral regurgitation is very rare. It is sometimes present in patients with Marfan syndrome, usually associated with a myxomatous prolapsing mitral valve.

D. Congenital Aortic Regurgitation

Congenital aortic regurgitation is rare. The most common causes are bicuspid aortic valve, with or without coarctation of the aorta; VSD with aortic cusp prolapse and aortic insufficiency; and fenestration of the aortic valve cusp (one or more holes in the cusp).

DISEASES OF THE AORTA

Although more common in mid to late adulthood, aortic dilation and dissection may occur in children. Although the aorta may not be dilated at birth, the structural abnormality that predisposes to dilation is presumed to be congenital. Patients at risk for progressive aortic dilation and dissection include those with isolated bicuspid aortic valve, Marfan syndrome, Turner syndrome, and type IV Ehlers-Danlos syndrome.

1. Bicuspid Aortic Valve

Patients with bicuspid aortic valves have an increased incidence of aortic dilation and dissection, regardless of the presence of aortic stenosis. Histologic examination demonstrates cystic medial degeneration of the aortic wall, similar to that seen in patients with Marfan syndrome. Patients with isolated bicuspid aortic valve require regular follow-up even in the absence of aortic insufficiency or aortic stenosis. Significant aortic root dilation requiring surgical intervention typically does not occur until adulthood.

2. Marfan Syndrome

Marfan syndrome is an autosomal dominant disorder of connective tissue caused by a mutation in the fibrillin-1 gene. Spontaneous mutations account for 25–30% of cases, and thus family history is not always helpful. Patients are diagnosed by the Ghent criteria and must have at a minimum, major involvement of two body systems plus involvement of a third body system or a positive family history. Body systems involved include cardiovascular, ocular, musculoskeletal, pulmonary, and integumentary. Cardiac manifestations include aortic root dilation and MVP, which may be present at birth. Patients are at risk for aortic dilation and dissection and are restricted from competitive athletics, contact sports, and isometric activities. β-Blockers or ACE inhibitors are used to lower blood pressure and slow the rate of aortic dilation. More recently, studies are ongoing to evaluate the effectiveness of angiotensin receptor blockers (losartan). Elective surgical

β-blockers or ACE inhibitors are used to lower blood pressure and slow the rate of aortic dilation. More recently, studies are ongoing to evaluate the effectiveness of angiotensin receptor blockers (losartan). Elective surgical
intervention is performed in patients of adult size when the aortic root dimension reaches 50 mm. The ratio of actual to expected aortic root dimension is used to determine the need for surgery in the young child. Surgical options include replacement of the dilated aortic root with a composite valve graft (Bentall technique) or a David procedure in which the patient’s own aortic valve is spared and a Dacron tube graft is used to replace the dilated ascending aorta. Young age at diagnosis was previously thought to confer a poor prognosis; however, early diagnosis with close follow-up and early medical therapy has been associated with more favorable outcome. Ventricular dysrythmias may contribute to the mortality in Marfan syndrome.

3. Turner Syndrome
Cardiovascular abnormalities are common in Turner syndrome. Patients are at risk for aortic dissection, typically during adulthood. Risk factors include hypertension regardless of cause, aortic dilation, bicuspid aortic valve, and coarctation of the aorta. There are rare reports of aortic dissection in adult Turner syndrome patients in the absence of any risk factors. Patients with Turner syndrome require routine follow-up from adolescence onward to monitor this potentially lethal complication.

CORONARY ARTERY ABNORMALITIES
Several anomalies involve the origin, course, and distribution of the coronary arteries. The only abnormality seen with regularity, and which has disastrous consequences if unrecognized, is anomalous origin of the left coronary artery.

Anomalous Origin of the Left Coronary Artery from the Pulmonary Artery (ALCAPA)
In this condition, the left coronary artery arises from the pulmonary artery rather than the aorta. In neonates, whose pulmonary artery pressure is high, perfusion of the left coronary artery may be adequate and the infant may be asymptomatic. By age 2 months the pulmonary arterial pressure falls, causing a progressive decrease in myocardial perfusion by the left coronary artery. Ischemia and infarction of the LV occur. Immediate surgery is needed to reimplant the left coronary artery and restore myocardial perfusion. The surgery is relatively high-risk, especially if infarction of the papillary muscles supporting the mitral apparatus has occurred. Mitral valve replacement will then sometimes be needed.

Clinical Findings
A. Symptoms and Signs
Neonates appear healthy and growth and development are relatively normal for a few months while pulmonary artery pressure is dropping. Detailed questioning may disclose a history of intermittent abdominal pain, pallor, and sweating, especially during or after feeding. Presentation may be subtle, with nonspecific complaints of “fussiness” or intermittent “colic.” The colic and fussiness are probably attacks of true angina. Presentation may be fulminant at age 2–4 months with sudden, severe HF due to LV dysfunction and mitral insufficiency. On physical examination, the infants are usually well developed and well nourished. The pulses are typically weak but equal. A prominent left precordial bulge is present. A holosystolic murmur of mitral regurgitation is sometimes present, though frequently auscultation alone reveals no obvious abnormalities.

B. Imaging
Chest radiographs show cardiac enlargement and left atrial enlargement and may show pulmonary venous congestion if left ventricular function has been compromised.

C. Electrocardiography
The ECG is very helpful. There is T-wave inversion in leads I and aVL. The precordial leads also show T-wave inversion from V₅–V₆. Deep and wide Q waves are present in leads I, aVL, and sometimes in V₅–V₆. These findings of myocardial infarction are similar to those in adults.

D. Echocardiography
The diagnosis can be made with two-dimensional echo techniques by visualizing a single large right coronary artery arising from the aorta and visualization of the anomalous left coronary artery arising from the main pulmonary artery. Flow reversal in the left coronary (heading toward the aorta, rather than away) confirms the diagnosis. LV dysfunction, echo-bright (ischemic) papillary muscles, and mitral regurgitation may be seen.

E. Cardiac Catheterization and Angiography
Angiogram of the aorta fails to show the origin of the left coronary artery. A large right coronary artery fills directly from the aorta, and contrast flows from the right coronary system via collaterals into the left coronary arteries and finally into the pulmonary artery. Angiogram of the RV or main pulmonary artery may show the origin of the anomalous vessel. Rarely, a left-to-right shunt may be detected as oxygenated blood passes through the collateral system without delivering oxygen to the myocardium, and passes into the pulmonary artery.
Treatment & Prognosis
Anomalous left coronary artery is a high-risk diagnosis. The prognosis is guarded at best. Medical management with diuretics and afterload reduction can help stabilize the ill patient, but surgical intervention should not be delayed. Most surgeons relocate the anomalous coronary button into the aorta. The mitral valve may have to be replaced, depending on the degree of mitral insufficiency.

CYANOTIC CONGENITAL HEART DISEASE
TETRALOGY OF FALLOT

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Hypoxemic spells during infancy.
- Right-sided aortic arch in 25% of patients.
- Systolic ejection murmur at the upper left sternal border.

General Considerations
In tetralogy of Fallot (ToF), a single embryologic abnormality causes multiple morphologic problems. Anterior deviation of the infundibular (pulmonary outflow) septum causes narrowing of the right ventricular outflow tract. This deviation also causes a VSD and the aorta overrides the crest of the ventricular septum. The RV hypertrophies, not because of pulmonary stenosis, but because it is pumping against systemic resistance across a (usually) large VSD. ToF is the most common cyanotic cardiac lesion and accounts for 10% of all congenital heart disease. A right-sided aortic arch is present in 25% of cases, and ASD occurs in 15%.

Obstruction to RV outflow with a large VSD causes a right-to-left shunt at the ventricular level with arterial desaturation. The greater the obstruction and the lower the systemic vascular resistance, the greater is the right-to-left shunt. ToF is associated with deletions in the long arm of chromosome 22 (22q11) in as many as 15% of affected children.

Clinical Findings

A. Symptoms and Signs
Clinical findings vary with the degree of RV outflow obstruction. Patients with mild obstruction are minimally cyanotic or acyanotic. Those with maximal obstruction are deeply cyanotic from birth. Few children are asymptomatic. Most have cyanosis by age 4 months, and the cyanosis usually is progressive, as subvalvular obstruction increases. Growth and development are not typically delayed, but easy fatigability and dyspnea on exertion are common. The fingers and toes show variable clubbing depending on age and severity of cyanosis. Historically, older children with ToF would frequently squat to increase systemic vascular resistance. This decreased the amount of right-to-left shunt, forcing blood through the pulmonary circuit, and would help ward off cyanotic spells. Squatting is rarely seen as the diagnosis is now made much earlier.

Hypoxic spells, also called cyanotic or “Tet spells,” are one of the hallmarks of severe ToF. They are characterized by (1) sudden onset of cyanosis or deepening of cyanosis; (2) dyspnea; (3) alterations in consciousness, from irritability to syncope; and (4) decrease or disappearance of the systolic murmur (as RV outflow tract flow becomes completely obstructed). These episodes most commonly start at age 4–6 months. Cyanotic spells are treated acutely by administration of oxygen and placing the patient in the knee-chest position. Intravenous morphine should be administered cautiously. Propranolol produces β-blockade and may reduce the obstruction across the RV outflow tract. Acidosis, if present, should be corrected with intravenous sodium bicarbonate. Chronic oral prophylaxis of cyanotic spells with propranolol may be useful to delay surgery but the onset of Tet spells usually prompts expedient intervention.

An RV lift is palpable. S₂ is predominantly aortic and single. A grade II–IV/VI, rough, systolic ejection murmur is present at the apex and radiates well to the back.

B. Laboratory Findings
Hemoglobin, hematocrit, and red blood cell count are usually elevated secondary to arterial desaturation.

C. Imaging
Chest radiographs show a normal size heart. The RV is hypertrophied, often shown by an upturning of the apex (boot-shaped heart). The main pulmonary artery segment is usually concave and, if there is a right aortic arch, the aortic knob is to the right of the trachea. The pulmonary vascular markings are usually decreased.

D. Electrocardiography
The QRS axis is rightward, ranging from +90 to +180 degrees. The P waves are usually normal. RVH is always present, but RV strain patterns are rare.

E. Echocardiography
Two-dimensional imaging is diagnostic, revealing thickening of the RV wall, overriding of the aorta, and a large subaortic VSD. Obstruction at the level of the infundibulum
and pulmonary valve can be identified, and the size of the proximal pulmonary arteries can be measured. The anatomy of the coronary arteries should be visualized, as abnormal branches crossing the RV outflow tract are at risk for transection during surgical enlargement of the area.

F. Cardiac Catheterization and Angiocardiography

Cardiac catheterization reveals a right-to-left shunt at the ventricular level in most cases. Arterial desaturation of varying degrees is present. The RV pressure is at systemic levels and the pressure tracing in the RV is identical to that in the LV if the VSD is large. The pulmonary artery pressure is invariably low. Pressure gradients may be noted at the valvular level, the infundibular level, or both. RV angiography reveals RV outflow obstruction and a right-to-left shunt at the ventricular level. The major indications for cardiac catheterization are to establish coronary artery and distal pulmonary artery anatomy.

Treatment

A. Palliative Treatment

A few centers currently advocate complete repair of ToF during the neonatal period regardless of patient size. Many centers prefer palliative treatment for small infants in whom complete correction is deemed risky. Medical palliation with long-term oral β-blocking agents may delay surgery. Some patients may be palliated by balloon dilation of the RV outflow tract during infancy. While this may improve the pulmonary blood flow and delay surgical intervention, hypercyanotic spells are frequent when the RV outflow tract is manipulated, making this procedure somewhat risky.

The most common surgical palliation is the insertion of a GoreTex shunt from the subclavian artery to the ipsilateral pulmonary artery (modified Blalock-Taussig shunt). This improves pulmonary blood flow regardless of the level of infundibular or valvular obstruction, and some believe, allows for growth of the patient’s pulmonary arteries (which are usually small) prior to complete surgical correction.

B. Total Correction

Open-heart surgery for repair of ToF is performed at ages ranging from birth to 2 years, depending on the experience of each center. The current surgical trend is toward earlier repair for symptomatic infants. The major limiting anatomic feature of total correction is the size of the pulmonary arteries. During surgery, the VSD is closed and the obstruction to RV outflow removed. Surgical mortality is low.

Course & Prognosis

Infants with severe ToF are usually deeply cyanotic at birth. These children require early surgery, either a Blalock-Taussig shunt or primary correction. All children with ToF require open-heart surgery. Complete repair before age 2 years usually produces a good result, and patients are currently living well into adulthood. Depending on the extent of the repair required, patients frequently require additional surgery 10–15 years after their initial repair for replacement of the pulmonary valve. Transcatheter pulmonary valves are under investigation and may help these patients avoid additional open-heart surgery in the future. The greatest risk for death in ToF patients is ventricular dysrhythmias. A competent pulmonary valve without a dilated RV appears to diminish arrhythmias and enhance exercise performance.

PULMONARY ATRESIA WITH VENTRICULAR SEPTAL DEFECT

This condition, complete atresia of the pulmonary valve in association with VSD, is essentially an extreme form of ToF. Because there is no antegrade flow from the RV to the pulmonary artery, pulmonary blood flow must be derived from a PDA or from multiple aortopulmonary collateral arteries (MAPCAs). Symptoms depend on the amount of pulmonary blood flow. If flow is significant, patients may be stable. If pulmonary flow is inadequate, severe hypoxemia occurs and immediate palliation is required. Newborns are stabilized with intravenous prostaglandin E\(_1\) (PGE\(_1\)) to maintain the PDA while being prepared for surgery. Rarely, if the ductus does not contribute significantly to pulmonary blood flow (ie, the MAPCAs alone are sufficient), PGE\(_1\) may be discontinued. Once stabilized, palliative aortopulmonary shunt or primary correction is undertaken. In most centers, a palliative shunt is performed in the newborn to augment pulmonary blood flow, and open-heart surgical correction planned for age 9–18 months.

Echocardiography is usually diagnostic. Cardiac catheterization and angiocardiography are required to confirm the source(s) of pulmonary blood flow. With small native pulmonary arteries and inadequate blood flow, an aortopulmonary shunt is created, either by rerouting the patient’s own vessels or by creating a shunt with artificial material. When the pulmonary arteries are large enough, relocation of the MAPCAs from the aorta to the pulmonary trunk (unifocalization) is performed to complete the repair.

Pulmonary vascular disease is common in pulmonary atresia with VSD, due both to intrinsic abnormalities of the pulmonary vasculature and to abnormal amounts of pulmonary blood flow. Even patients who have undergone surgical correction as infants are at risk. Pulmonary vascular disease is a common cause of death as early as the third decade of life.
PULMONARY ATRESIA WITH INTACT VENTRICULAR SEPTUM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Completely different from pulmonary atresia with VSD.
- Cyanosis at birth.
- Always ductal dependent with rare aortopulmonary collateral arteries.
- RV-dependent coronary arteries sometimes are present.

General Considerations

Although pulmonary atresia with intact ventricular septum (PA/IVS) sounds as if it might be related to pulmonary atresia with VSD, it is a distinct cardiac condition. As the name suggests, the pulmonary valve is atretic. The pulmonic annulus usually has a small diaphragm consisting of the fused valve cusps. The ventricular septum is intact. The main pulmonary artery segment is usually present and closely approximated to the atretic valve, but is somewhat hypoplastic. Although the RV is always reduced in size, the degree of reduction is variable. The size of the RV is critical to the success of surgical repair. In some children with PA/IVS, the RV is adequate for ultimate two-ventricular repair. A normal RV has three component parts (inlet, trabecular or body, and outlet). The absence of any one of the components makes adequate RV function unlikely. Even with all three components, some RVs are inadequate.

After birth, the pulmonary circulation is maintained by the ductus arteriosus. Multiple aortopulmonary collateral arteries are usually not present in this disease, in contrast to pulmonary atresia with VSD. A continuous infusion of PGE1, must be started as soon as possible after birth to maintain ductal patency.

Clinical Findings

A. Symptoms and Signs

Neonates are usually cyanotic and become more so as the ductus arteriosus closes. A blowing systolic murmur resulting from the associated PDA may be heard at the pulmonary area. A holosystolic murmur is often heard at the lower left sternal border, as many children develop tricuspid insufficiency if the RV is of good size and egress from that ventricle is only through the tricuspid valve.

B. Imaging

The heart size varies from small to markedly enlarged depending on the degree of tricuspid insufficiency. With severe tricuspid insufficiency, right atrial enlargement may be massive and the cardiac silhouette may fill the chest on radiograph.

C. Electrocardiography

ECG reveals a left axis for age (45–90 degrees) in the frontal plane. Left ventricular forces dominate the ECG, and there is a paucity of RV forces, particularly with hypoplastic RV. Findings of right atrial enlargement are usually striking.

D. Echocardiography

Echocardiography shows atresia of the pulmonary valve with varying degrees of RV cavity and tricuspid annulus hypoplasia. The severity of tricuspid regurgitation correlates with RV size.

E. Cardiac Catheterization and Angiocardiography

RV pressure is almost always suprasystemic. Angiogram of the RV reveals no filling of the pulmonary artery. It also demonstrates the size of the RV chamber, relative hypoplasia of the three components of the RV, and the presence or absence of tricuspid regurgitation. Some children with pulmonary atresia and an intact ventricular septum have sinusoids between the RV and the coronary arteries. The presence of sinusoids indicates that the coronary circulation may depend on high right ventricular pressure. Any attempt to decompress the RV in patients with RV-dependent coronary circulation causes myocardial infarction and death because of the precipitous decrease in coronary perfusion.

Treatment & Prognosis

As in all ductal-dependent lesions, PGE1 is used to stabilize the patient and maintain patency of the ductus until surgery can be performed. Surgery is usually undertaken in the first week of life. Unrestricted flow through the ASD is a necessity, since the only outflow from the right atrium is via the atrial defect and into the left atrium.

A Rashkind balloon atrial septostomy may be required, depending on RV size, to open a communication across the atrial septum. If the RV is tripartite and an eventual two-chamber repair is planned, the pulmonary valve plate may be perforated and dilated during cardiac catheterization in the newborn to allow antegrade flow from the RV to the pulmonary artery and thus encourage RV cavity growth. If the RV is inadequate, if significant sinusoids are present, or if the pulmonic valve cannot be opened successfully during cardiac catheterization, a Blalock-Taussig shunt is performed to establish pulmonary blood flow. Later in infancy, a communication between the RV and pulmonary artery can be created to stimulate RV cavity growth. If either RV dimen-
sion or function is inadequate for two-ventricular repair, an approach similar to that taken for a single ventricle pathway best serves these children (see section on Hypoplastic Left Heart Syndrome, later). Children with significant sinusoids are often considered for cardiac transplantation if they are at risk for coronary insufficiency and sudden death.

The prognosis in this condition is guarded. Experience strongly favors opening the atretic valve in the catheterization laboratory in the newborn period if possible. Ultimate plans for two-ventricular repair, Fontan procedure, or cardiac transplantation depend on the anatomy.

TRICUSPID ATRESIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Marked cyanosis present from birth.
ECG with left axis deviation, right atrial enlargement, and LVH.

General Considerations

In tricuspid atresia, there is complete atresia of the tricuspid valve with no direct communication between the right atrium and the RV. There are two types of tricuspid atresia based on the relationship of the great arteries. The entire systemic venous return must flow through the atrial septum (either ASD or patent foramen ovale) to reach the left atrium. The left atrium thus receives both the systemic venous return and the pulmonary venous return. Complete mixing occurs in the left atrium, resulting in variable degrees of arterial desaturation.

Because there is no flow to the RV, development of the RV depends on the presence of a ventricular left-to-right shunt. Severe hypoplasia of the RV occurs when there is no VSD or when the VSD is small.

Clinical Findings

A. Symptoms and Signs

Symptoms usually develop in early infancy with cyanosis present at birth in most infants. Growth and development are poor, and the infant usually exhibits exhaustion during feedings, tachypnea, and dyspnea. Patients with an increased pulmonary blood flow—types 1(c) and 2(b)—may develop HF with less prominent cyanosis. A murmur from the VSD is usually present and heard best at the lower left sternal border. Digital clubbing is present in older children with long standing cyanosis.

B. Imaging

The heart is slightly to markedly enlarged. The main pulmonary artery segment is usually small or absent. The size of the right atrium is moderately to massively enlarged, depending on the size of the communication at the atrial level. The pulmonary vascular markings are usually decreased. Pulmonary vascular markings may be increased if pulmonary blood flow is not restricted by the VSD or pulmonary stenosis.

C. Electrocardiography

The ECG shows marked left axis deviation. The P waves are tall and peaked, indicative of right atrial hypertrophy. LVH or LV dominance is found in almost all cases. RV forces on the ECG are usually low or absent.

D. Echocardiography

Two-dimensional methods are diagnostic and show absence of the tricuspid valve, the relationship between the great arteries, and the size of the pulmonary arteries. Color-flow Doppler imaging can help identify levels of restriction of pulmonary blood flow, either at the VSD or in the RV outflow tract.

E. Cardiac Catheterization and Angiocardiography

Catheterization reveals a right-to-left shunt at the atrial level. Because of mixing in the left atrium, oxygen saturations in the LV, RV, pulmonary artery, and aorta are identical to that in the left atrium. Right atrial pressure is increased if the ASD is restrictive. LV and systemic pressures are normal. The catheter cannot be passed through the tricuspid valve from the right atrium to the RV. A balloon atrial septostomy is performed if a restrictive foramen ovale or ASD is present.

Treatment & Prognosis

In infants with unrestricted pulmonary blood flow, conventional anticongestive therapy with diuretics and afterload reduction should be given until the infant begins to outgrow the VSD. Sometimes, a pulmonary artery band is needed to protect the pulmonary bed from excessive flow.

Staged palliation of tricuspid atresia is the usual surgical approach. In infants with diminished pulmonary blood flow, PGE1 is given until an aortopulmonary shunt can be performed. A Glenn procedure (superior vena cava to pulmonary artery anastomosis) is done with takedown of the aortopulmonary shunt at 4–6 months when saturations begin to fall, and completion of the Fontan procedure (redirection of inferior vena cava and superior vena cava to pulmonary artery) is performed when the child reaches around 15 kg.

The prognosis for patients with tricuspid atresia depends on achieving a pulmonary blood flow that permits adequate
oxygenation of the tissues without producing HF. The long-term prognosis for children treated by the Fontan procedure is unknown, although patients now are living into their late 20s and early 30s. In the short term, the best results for the Fontan procedure occur in children with low pulmonary artery pressures prior to open-heart surgery.

HYPOPLASTIC LEFT HEART SYNDROME

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Mild cyanosis at birth.
- Minimal auscultatory findings.
- Rapid onset of shock with ductal closure.

General Considerations

Hypoplastic left heart syndrome (HLHS) includes several conditions in which lesions of the left heart result in hypoplasia of the LV. The syndrome occurs in 1.4–3.8% of infants with congenital heart disease.

Stenosis or atresia of the mitral and aortic valves is the rule. In the neonate, survival depends on a PDA because antegrade flow into the systemic circulation is inadequate or nonexistent. The PDA provides the only flow to the aorta. Children with HLHS are usually stable at birth, but they deteriorate rapidly as the ductus closes in the first week of life. Untreated, the average age at death is the first week of life. Rarely, the ductus remains patent and infants may survive for several months without PGE1 therapy.

Currently, in settings with the expertise, the diagnosis is made prepartum by fetal echocardiography. Prepartum diagnosis aids greatly in planning for the delivery of the infant at or near a center with experience in treating HLHS.

Clinical Findings

A. Symptoms and Signs

Neonates with HLHS appear stable at birth because the ductus is patent. They deteriorate rapidly as the ductus closes, with shock and acidosis secondary to inadequate systemic perfusion. Oxygen saturation may initially increase as more blood flows to the lungs with ductal closure.

B. Imaging

Chest radiograph at presentation shows cardiac enlargement with severe pulmonary venous congestion if the PDA has begun closing. Chest radiograph in the first day of life may be relatively unremarkable, with the exception of a small cardiac silhouette.

C. Electrocardiography

The ECG shows right axis deviation, right atrial enlargement, and RVH with a relative paucity of LV forces. The small Q wave in lead V6 may be absent, and a qR pattern is often seen in lead V1.

D. Echocardiography

Echocardiography is diagnostic. A very small aorta and LV with atretic or severely stenotic mitral and aortic valves are diagnostic. The systemic circulation is dependent on the PDA. Color-flow Doppler imaging shows retrograde flow in the ascending aorta, as the coronary arteries must be supplied by the ductus via the small native aorta.

Treatment & Prognosis

PGE1 is essential initially, as systemic circulation depends on a patent ductus arteriosus. Later management depends on balancing pulmonary and systemic blood flow both of which depend on the RV. At a few days of age the pulmonary resistance falls, favoring pulmonary overcirculation and systemic underperfusion. Therapy is then directed at encouraging systemic blood flow. Nitrogen is used to decrease inspired oxygen to as low as 17%. This therapy must be carefully monitored but results in increased pulmonary arterial tone and better systemic perfusion. Systemic afterload reduction will also increase systemic perfusion. Adequate perfusion can usually be obtained by keeping systemic O2 saturation between 65% and 80%, or more accurately a Po2 of 40 mm Hg.

A choice must be made shortly after birth among several treatment options. In the Norwood procedure, the relatively normal main pulmonary artery is transected and connected to the small ascending aorta. The aortic arch must be reconstructed due to its small size. Then, either a Blalock-Taussig shunt (from the subclavian artery to the pulmonary artery) or a Sano shunt (from the RV to the pulmonary artery) must be created to restore pulmonary blood flow. Children who have a Norwood procedure will later require a Glenn anastomosis (superior vena cava to pulmonary artery with takedown of the systemic-pulmonary shunt) and then a Fontan (inferior vena cava to pulmonary artery, completing the systemic venous bypass of the heart) at ages 6 months and 2–3 years, respectively. Although this is a major improvement over nonsurgical intervention, HLHS remains one of the most challenging lesions in pediatric cardiology, as survival is still only 60% at 5 years.

Orthotopic heart transplantation is also a treatment for HLHS. Survival after transplantation is better than survival after the Norwood operation, but death while awaiting transplantation increases overall mortality to the same level as the Norwood.
Recently, many centers have moved toward a “hybrid” approach to HLHS as a result of collaboration between surgeons and interventional cardiologists. In the hybrid procedure, the chest is opened surgically and the pulmonary arteries are banded, to limit pulmonary blood flow. Then, also through the open chest, a PDA stent is placed by the interventionalist to maintain systemic output. The second stage is considered a “comprehensive Glenn,” in which the pulmonary artery bands and ductal stent are taken down, and the superior vena cava is surgically connected to the pulmonary arteries. Aortic arch reconstruction is done during the second stage, in contrast to the Norwood operation. Survival after the first-stage “hybrid” is greater than 90% at the most experienced centers. Long-term follow-up is not yet available.

**TRANSPOSITION OF THE GREAT ARTERIES**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Cyanotic newborn without respiratory distress.
- More common in males.

**General Considerations**

Transposition of the great arteries (TGA) is the second most common cyanotic congenital heart disease, accounting for 5% of all cases of congenital heart disease. The male-to-female ratio is 3:1. It is caused by an embryologic abnormality in the spiral division of the truncus arteriosus in which the aorta arises from the RV and the pulmonary artery from the LV. This is referred to as “ventriculoarterial discordance.” Patients may have a VSD, or the ventricular septum may be intact. Left unrepaired, transposition is associated with a high incidence of early pulmonary vascular obstructive disease. Because pulmonary and systemic circulations are in parallel, survival is impossible without mixing between the two circuits. The PDA and the patent foramen ovale are critically important. The majority of mixing occurs at the atrial and ductal levels. These communications are frequently inadequate at birth, and patients are therefore severely cyanotic.

**Clinical Findings**

**A. Symptoms and Signs**

Many neonates are large (up to 4 kg) and profoundly cyanotic without respiratory distress or a significant mur-
Survival after the ASO is greater than 95% in major centers. The switch procedure greatly shortens the duration of severe cyanosis before corrective surgery. Early relief of cyanosis may improve the developmental outcome. Finally, the switch procedure leaves the LV as the systemic ventricle. The older atrial corrective procedures left the RV in this role and there was a significant late RV failure.

Cohen MS et al: Is the arterial switch operation as good over the long term as we thought it would be? Cardiol Young 2006;16(Suppl 3):117 [PMID: 17378050].

1. Congenitally Corrected Transposition of the Great Arteries

Congenitally corrected transposition of the great arteries (ccTGA) is a relatively uncommon congenital heart disease. Patients may present with cyanosis, depending on the associated lesions. In ccTGA, both atrioventricular and ventriculoarterial discordance occurs so that the right atrium connects to a morphologic LV, which supports the pulmonary artery. Conversely, the left atrium empties via a tricuspid valve into a morphologic RV, which supports the aorta. Common associated lesions are VSD and pulmonary stenosis. A dysplastic left-sided tricuspid valve is almost always present. In the absence of associated lesions, patients with ccTGA are often undiagnosed until adulthood when they present with left-sided AV valve insufficiency or arrhythmias.

Previously, surgical repair was directed at VSD closure and relief of pulmonary outflow tract obstruction—a technique that maintained the RV as the systemic ventricle supporting the aorta. It is now recognized that these patients have a reduced life span; thus other surgical techniques have been advocated. The double-switch procedure is one such technique. An atrial level switch (Mustard or Senning technique) is performed, in which pulmonary and systemic venous blood are baffled across the atrial mass in a way that prevents mixing and drains into the contralateral ventricle. An ASO then restores the morphologic LV to its position as systemic ventricle.

Patients with ccTGA have an increased incidence of complete heart block with an estimated risk of 1% per year and an overall frequency of 50%.

2. Double-Outlet Right Ventricle

In this uncommon malformation, both great arteries arise from the RV. There is always a VSD that allows blood to exit the LV. Presenting symptoms depend on the relationship of the VSD to the semilunar valves. The VSD can be in variable positions, and the great arteries could be normally related or malposed. In the absence of outflow obstruction, a large left-to-right shunt exists and the clinical picture resembles that of a large VSD. Pulmonary stenosis may be present, particularly if the VSD is remote from the pulmonary artery. This physiology is similar to ToF. Alternatively, if the VSD is nearer the pulmonary artery, aortic outflow may be obstructed (called the Taussig-Bing malformation). Early primary correction is the goal. LV flow is directed to the aorta across the VSD, and frequently an RV-pulmonary artery conduit is placed to maintain an unobstructed pulmonary circuit. If the aorta is far from the VSD, an arterial switch may be necessary. Echocardiography is usually sufficient to make the diagnosis and determine the orientation of the great vessels and their relationship to the VSD.

**TOTAL ANOMALOUS PULMONARY VENOUS RETURN**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Abnormal pulmonary venous connection leading to cyanosis.
- Occurs with or without murmur and may have accentuated P2.
- Right atrial enlargement and RVH.

**General Considerations**

This malformation accounts for 2% of all congenital heart lesions. The pulmonary venous blood drains into a confluence behind the left atrium, but the confluence is not connected to the left atrium. The pulmonary venous blood finds another route to rejoin the circulation via the larger systemic veins. This leads to complete mixing at the level of the right atrium. The presentation of total anomalous pulmonary venous return (TAPVR) depends on the route of return to the systemic circulation and whether or not the return is obstructed.

The malformation is classified by the site of entry of the pulmonary venous drainage into the right side of the heart. Supradiaphragmatic return is defined as a confluence that drains into the right superior vena cava, innominate vein or persistent left superior vena cava. In infradiaphragmatic return the confluence returns below the diaphragm usually.
into the portal venous system which empties into the inferior vena cava. Infra-diaphragmatic pulmonary venous return is essentially always obstructed. It is a surgical emergency. Supradiaphragmatic veins may also be obstructed, though less commonly. Rarely, pulmonary veins can drain directly to the right atrium, or a single confluence may drain to more than one location, called mixed TAPVR.

Because the entire venous drainage from the body comes to the right atrium, a right-to-left shunt must be present at the atrial level, either as an ASD or a patent foramen ovale. Occasionally the atrial septum is restrictive and balloon septostomy is needed at birth to allow filling of the left heart.

#### Clinical Findings

**A. Unobstructed Pulmonary Venous Return**

Patients with a large atrial communication tend to have high pulmonary blood flow and typically present with cardiomegaly and HF rather than cyanosis. Oxygen saturations in the high 80s or low 90s are common. Most patients in this group have mild to moderate elevation of pulmonary artery pressure owing to elevated pulmonary blood flow. In most instances, PA pressure does not reach systemic levels.

**1. Symptoms and signs**—Patients may have mild cyanosis in the neonatal period and early infancy. Thereafter, they do relatively well except for frequent respiratory infections. They are usually small and thin, resembling patients with other large left-to-right shunts. Examination discloses dusky nail beds and mucus membranes, but overt cyanosis and digital clubbing are usually absent. The arterial pulses are normal. An RV heave is palpable, and P₂ is increased. A systolic and diastolic murmur may be heard as a result of increased flow across the pulmonary and tricuspid valves, respectively.

**2. Imaging**—Chest radiography reveals cardiomegaly involving the right heart and pulmonary artery. Pulmonary vascular markings are increased. The characteristic cardiac contour called a “snowman” or “figure 8” is often seen when the anomalous veins drain via a persistent left superior vena cava to the innominate vein and then the right superior vena cava, but this is not apparent until about 3 months of age when the vertical and innominate vein have dilated.

**3. Electrocardiography**—ECG shows right axis deviation and varying degrees of right atrial enlargement and right ventricular hypertrophy. A qR pattern is often seen over the right precordial leads.

**4. Echocardiography**—Demonstration by echocardiography of a discrete chamber posterior to the left atrium is strongly suggestive of the diagnosis. The availability of two-dimensional echocardiography plus color-flow Doppler has increased diagnostic accuracy such that diagnostic cardiac catheterization is rarely required.

**B. With Obstructed Pulmonary Venous Return**

This group includes all patients with infra-diaphragmatic TAPVR and a few of the patients in whom venous drainage is into a systemic vein above the diaphragm.

**1. Symptoms and signs**—Infants usually present shortly after birth with severe cyanosis and require early corrective surgery. Cardiac examination discloses a striking RV impulse. S₁ is accentuated and S₂ is markedly accentuated and single. There is no murmur in many cases. Sometimes, a systolic murmur is heard over the pulmonary area with radiation over the lung fields. Diastolic murmurs are uncommon.

**2. Imaging**—The heart is usually small and pulmonary venous congestion severe with associated air bronchograms. The chest radiographic appearance may lead to an erroneous diagnosis of severe lung disease. In less severe cases, the heart size may be normal or slightly enlarged with mild pulmonary venous congestion.

**3. Electrocardiography**—The ECG shows right axis deviation, right atrial enlargement, and RVH.

**4. Echocardiography**—Echocardiography shows a small left atrium and LV. For infra-diaphragmatic TAPVR, appearance of a vessel lying parallel and anterior to the descending aorta and to the left of the inferior vena cava may represent the vein draining the confluence caudally toward the diaphragm. Color-flow Doppler echocardiography may reveal flow disturbance, commonly near the confluence or in the liver, where flow is obstructed.

**5. Cardiac catheterization and angiography**—If echocardiography does not confirm the anatomy, cardiac catheterization and angiography demonstrate the site of entry of the anomalous veins. Catheterization can also assist in calculating the ratio of pulmonary to systemic blood flow and the degree of pulmonary hypertension and pulmonary vascular resistance.

#### Treatment

Surgery is always required for TAPVR. If pulmonary venous return is obstructed, surgery must be performed immediately. In unobstructed TAPVR, surgery may be delayed for weeks to months. The timing of surgery is determined by the child’s weight gain and the risk of pulmonary infection. If early surgery is not required and the atrial septum is restrictive, a balloon atrial septostomy can be performed in newborns.

#### Course & Prognosis

Most children with TAPVR do well after surgery. Some surgical survivors develop late stenosis of the pulmonary veins. Pulmonary vein stenosis is an intractable condition that is difficult to treat either with interventional catheterization or surgery and has a poor prognosis. By avoiding direct suturing at the pulmonary venous ostia, the chance of
re recurrent stenosis at the anastomotic site is lessened. Unfortunately, any manipulation of the pulmonary veins increases the risk of stenosis.

TRUNCUS ARTERIOSUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Early HF with or without cyanosis.
- Systolic ejection click.

General Considerations

Truncus arteriosus accounts for less than 1% of congenital heart malformations. A single great artery arises from the heart, giving rise to the systemic, pulmonary, and coronary circulations. Truncus develops embryologically as a result of failure of the division of the common truncus arteriosus into the aorta and the pulmonary artery. A VSD is always present. The number of truncal valve leaflets varies from two to six, and the valve may be insufficient or stenotic.

Truncus arteriosus is divided into subtypes by the anatomy of the pulmonary circulation. A single main pulmonary artery may arise from the base of the trunk and gives rise to branch pulmonary arteries (type 1). Alternatively, the pulmonary arteries may arise separately from the common trunk, either in close association with one another (type 2) or widely separated (type 3).

In patients with truncus, blood from both ventricles leaves the heart through a single exit. Thus, oxygen saturation in the pulmonary artery is equal to that in the systemic arteries. The degree of systemic arterial oxygen saturation depends on the ratio of pulmonary to systemic blood flow. If pulmonary vascular resistance is normal, the pulmonary blood flow is greater than the systemic blood flow and the saturation is relatively high. If pulmonary vascular resistance is elevated because of pulmonary vascular obstructive disease or small pulmonary arteries, pulmonary blood flow is reduced and oxygen saturation is low. The systolic pressures are systemic in both ventricles.

Clinical Findings

A. Symptoms and Signs

High pulmonary blood flow characterizes most patients with truncus arteriosus. These patients are usually acyanotic and present in HF. Examination of the heart reveals a hyperactive precordium. A systolic thrill is common at the lower left sternal border. A loud early systolic ejection click is commonly heard. \( S_1 \) is single and accentuated. A loud holosystolic murmur is audible at the left lower sternal border. A diastolic flow murmur can often be heard at the apex due to increased pulmonary venous return crossing the mitral valve. An additional diastolic murmur of truncal insufficiency may be present.

Patients with decreased pulmonary blood flow are cyanotic early. The most common manifestations are growth retardation, easy fatigability, and HF. The heart is not hyperactive. \( S_1 \) and \( S_2 \) are single and loud. A systolic murmur is heard at the lower left sternal border. No mitral flow murmur is heard, as pulmonary venous return is decreased. A loud systolic ejection click is commonly heard.

B. Imaging

The common radiographic findings are a boot-shaped heart, absence of the main pulmonary artery segment, and a large aorta that has a right arch 30% of the time. The pulmonary vascular markings vary with the degree of pulmonary blood flow.

C. Electrocardiography

The axis is usually normal. RVH or combined ventricular hypertrophy is commonly present.

D. Echocardiography

Images generally show override of a single great artery (similar to ToF, but no second great artery arises directly from the heart). The origin of the pulmonary arteries and the degree of truncal valve abnormality can be seen. Color-flow Doppler can aid in the description of pulmonary flow and the function of the truncal valve, both of which are critical to management.

E. Angiocardiography

Cardiac catheterization is not routinely performed but may be of value in older infants in whom pulmonary vascular disease must be ruled out. The single most important angiogram would be from the truncal root, as both the origin of the pulmonary arteries and the amount of truncal insufficiency would be seen from one injection.

Treatment

Anticongestive measures are needed for patients with high pulmonary blood flow and congestive failure. Surgery is always required in this condition. Because of HF, surgery is usually performed in the neonatal period. The VSD is closed to allow LV egress to the truncal valve. The pulmonary artery (type 1) or arteries (types 2–3) are separated from the truncus as a block, and a valved conduit is fashioned from the RV to the pulmonary circulation.
**Course & Prognosis**

Children with a good surgical result generally do well. Similar to patients with ToF, they almost always outgrow the RV-to-pulmonary artery conduit placed in infancy and require revision of the conduit in later childhood. The risk of early pulmonary vascular obstructive disease is high in the unrepaired patient and a decision to delay open-heart surgery beyond age 4–6 months is not wise even in stable patients.

**ACQUIRED HEART DISEASE**

**RHEUMATIC FEVER**

Rheumatic fever remains a major cause of morbidity and mortality in developing countries that suffer from poverty, overcrowding, and poor access to health care. Even in developed countries, rheumatic fever has not been entirely eradicated. The overall incidence in the United States is less than 1 per 100,000. There have been regional resurgences, such as in Utah in the 1980s, with an incidence of nearly 12 per 100,000 children between the ages of 3 and 17 years.

Group A β-hemolytic streptococcal infection of the upper respiratory tract is the essential trigger in predisposed individuals. Only certain serotypes of group A *Streptococcus* cause rheumatic fever. The latest attempts to define host susceptibility implicate immune response genes that are present in approximately 15% of the population. The immune response triggered by colonization of the pharynx with group A streptococci consists of (1) sensitization of B lymphocytes by streptococcal antigens, (2) formation of antistreptococcal antibody, (3) formation of immune complexes that cross-react with cardiac sarcolemma antigens, and (4) myocardial and valvular inflammatory response.

The peak age of risk in the United States is 5–15 years. The disease is slightly more common in girls and in African Americans. The annual death rate from rheumatic heart disease in school-aged children (whites and nonwhites) recorded in the 1980s was less than 1 per 100,000.

**Clinical Findings**

Two major or one major and two minor manifestations (plus supporting evidence of streptococcal infection) based on the modified Jones criteria are needed for the diagnosis of acute rheumatic fever (Table 19–14). Except in cases of rheumatic fever manifesting solely as Sydenham chorea or long-standing carditis, there should be clear evidence of a streptococcal infection such as scarlet fever, a positive throat culture for group A β-hemolytic *Streptococcus*, and increased antistreptolysin O or other streptococcal antibody titers. The antistreptolysin O titer is significantly higher in rheumatic fever than in uncomplicated streptococcal infections.

### A. Carditis

Carditis is the most serious consequence of rheumatic fever and varies from minimal to life-threatening HF. The term carditis implies pancardiac inflammation, but it may be limited to valves, myocardium, or pericardium. Valvulitis is frequently seen, with the mitral valve most commonly affected. Mitral insufficiency is the most common valvular residua of acute rheumatic carditis. Mitral stenosis after acute rheumatic fever is rarely encountered until 5–10 years after the first episode. Thus, mitral stenosis is much more commonly seen in adults than in children.

An early decrescendo diastolic murmur consistent with aortic insufficiency is occasionally encountered as the sole valvular manifestation of rheumatic carditis. The aortic valve is the second most common valve affected in polyvalvular as well as in single-valve disease. The aortic valve is involved more often in males and in African Americans. Dominant aortic stenosis of rheumatic origin does not occur in pediatric patients. In one large study, the shortest length of time observed for a patient to develop dominant aortic stenosis secondary to rheumatic heart disease was 20 years.

### B. Polyarthritis

The large joints (knees, hips, wrists, elbows, and shoulders) are most commonly involved and the arthritis is typically migratory. Joint swelling and associated limitation of move-

ment should be present. This is one of the more common major criteria, occurring in 80% of patients. Arthralgia alone is not a major criterion.

C. Sydenham Chorea

Sydenham chorea is characterized by involuntary and purposeless movements and is often associated with emotional lability. These symptoms become progressively worse and may be accompanied by ataxia and slurring of speech. Muscular weakness becomes apparent following the onset of the involuntary movements. Chorea is self-limiting, although it may last up to 3 months. Chorea may not be apparent for months to years after the acute episode of rheumatic fever.

D. Erythema Marginatum

A macular, serpiginous, erythematous rash with a sharply demarcated border appears primarily on the trunk and the extremities. The face is usually spared.

E. Subcutaneous Nodules

These usually occur only in severe cases, and then most commonly over the joints, scalp, and spinal column. The nodules vary from a few millimeters to 2 cm in diameter and are nontender and freely movable under the skin.

Treatment & Prophylaxis

A. Treatment of the Acute Episode

1. Anti-infective therapy—Eradication of the streptococcal infection is essential. Long-acting benzathine penicillin is the drug of choice. Depending on the age and weight of the patient, give a single intramuscular injection of 0.6–1.2 million units; alternatively, give penicillin V, 125–250 mg orally four times a day for 10 days. Erythromycin, 250 mg orally four times a day, may be substituted if the patient is allergic to penicillin.

2. Anti-inflammatory agents

a. Aspirin—Aspirin, 30–60 mg/kg/d, is given in four divided doses. This dose is usually sufficient to effect dramatic relief of arthritis and fever. Higher dosages carry a greater risk of side effects and there are no proven short- or long-term benefits of high doses that produce salicylate blood levels of 20–30 mg/dL. The duration of therapy is tailored to meet the needs of the patient, but 2–6 weeks of therapy with reduction in dose toward the end of the course is usually sufficient. Other nonsteroidal anti-inflammatory agents used because of concerns about Reye syndrome are less effective than aspirin.

b. Corticosteroids—Corticosteroids are seldom indicated except in the rare patient with severe carditis and HF, in whom they may be lifesaving. Steroids are given as follows: prednisone, 2 mg/kg/d orally for 2 weeks; reduce prednisone to 1 mg/kg/d during the third week, and begin aspirin, 50 mg/kg/d; stop prednisone at the end of 3 weeks, and continue aspirin for 8 weeks or until the C-reactive protein is negative and the sedimentation rate is falling.

3. Therapy in heart failure—Treatment for HF is based on symptoms and severity of valve involvement and cardiac dysfunction (see section on Heart Failure, earlier).

4. Bed rest and ambulation—Bed rest is not required in most cases. Activity level should be commensurate with symptoms and children should be allowed to self-limit their activity level while affected. Children should not return to school while there is clear evidence of rheumatic activity. Most acute episodes of rheumatic fever are managed on an outpatient basis.

B. Treatment after the Acute Episode

1. Prevention—Prevention is critical, as patients who have had rheumatic fever are at greater risk of recurrence if future group A β-hemolytic streptococcal infections are inadequately treated. Follow-up visits are essential to reinforce the necessity for prophylaxis with regular long-acting benzathine penicillin. Intramuscular rather than oral medication is associated with better adherence and is the preferred method of prophylaxis. If myocardial or valvular disease persists, antibacterial prophylaxis is a lifelong commitment. More commonly with transient or no cardiac involvement, 3–5 years of therapy or discontinuance in early adulthood (age 21) is an effective approach.

The following preventive regimens are in current use:

a. Penicillin G benzathine—1.2 million units intramuscularly every 21–28 days is the drug of choice.

b. Sulfadiazine—500 mg daily as a single oral dose for patients weighing more than 27 kg is the drug of second choice. Blood dyscrasias and lesser effectiveness in reducing streptococcal infections make this drug less satisfactory than penicillin benzathine G.

c. Penicillin V—250,000 units orally twice daily offers approximately the same protection afforded by sulfadiazine but is much less effective than intramuscular penicillin benzathine G (5.5 versus 0.4 streptococcal infections per 100 patient-years).

d. Erythromycin—250 mg orally twice a day may be given to patients who are allergic to both penicillin and sulfonamides.

2. Residual valvular damage—As described above, the mitral and aortic valves are most commonly affected by rheumatic fever and the severity of carditis is quite variable. In the most severe cases, cardiac failure or the need for a valve replacement can occur in the acute setting. In less severe cases, valve abnormalities can persist, requiring lifelong medical management and eventual valve replacement. Other patients fully recover without residual cardiac sequelae.
CHAPTER 19

KAWASAKI DISEASE

Kawasaki disease was first described in Japan in 1967 and was initially called mucocutaneous lymph node syndrome. The cause is unclear and there is no specific diagnostic test. Kawasaki disease is the leading cause of acquired heart disease in children in the United States. Eighty percent of patients are younger than 5 years old (median age at diagnosis is 2 years), and the male-to-female ratio is 1.5:1. Diagnostic criteria are fever for more than 5 days and at least four of the following features: (1) bilateral, painless, nonexudative conjunctivitis; (2) lip or oral cavity changes (eg, lip cracking and fissuring, strawberry tongue, and inflammation of the oral mucosa); (3) cervical lymphadenopathy ≥ 1.5 cm in diameter and usually unilateral; (4) polymorphous exanthema; and (5) extremity changes (redness and swelling of the hands and feet with subsequent desquamation). Clinical features not part of the diagnostic criteria, but frequently associated with Kawasaki disease, are shown in Table 19–15.

The potential for cardiovascular complications is the most serious aspect of Kawasaki disease. Complications during the acute illness include myocarditis, pericarditis, valvular heart disease (usually mitral or aortic regurgitation), and coronary arteritis. Patients with fever for at least 5 days but fewer than four of the diagnostic features can be diagnosed with atypical Kawasaki disease if they have coronary artery abnormalities detected by echocardiography.

Coronary artery lesions range from mild transient dilation of a coronary artery to large aneurysms. Aneurysms rarely form before day 10 of illness. Untreated patients have a 15–25% risk of developing coronary aneurysms. Those at greatest risk of aneurysm are males, young children (< 6 months), and those not treated with intravenous immunoglobulin (IVIG). Most coronary artery aneurysms resolve within 5 years of diagnosis; however, as aneurysms resolve, associated obstruction or stenosis (19% of all aneurysms) may develop, which may result in coronary ischemia. Giant aneurysms (> 8 mm) are less likely to resolve, and nearly 50% eventually become stenotic. Of additional concern, acute thrombosis of an aneurysm can occur, resulting in myocardial infarction that is fatal in approximately 20% of cases.

Treatment

Immediate management of Kawasaki disease is IVIG and high-dose aspirin. This therapy is effective in decreasing the incidence of coronary artery dilation and aneurysm formation. The currently recommended regimen is 2 g/kg of IVIG administered over 10–12 hours and 80–100 mg/kg/d of aspirin in four divided doses. The duration of high-dose aspirin is institution-dependent: many centers reduce the dose once the patient is afebrile for 48–72 hours; others continue through day 14 of the illness. Once high-dose aspirin is discontinued, low-dose aspirin (3–5 mg/kg/d) is given through the subacute phase of the illness (6–8 weeks) or until coronary artery abnormalities resolve. If fever recurs within 48–72 hours of the initial treatment course and no other source of the fever is detected, a second dose of IVIG is often recommended; however, the effectiveness of this approach has not been clearly demonstrated. A recent multicenter, randomized, double-blind, placebo-controlled study (Newburger et al) demonstrated no beneficial effect of pulsed corticosteroids on the development of coronary abnormalities in patients responsive to IVIG. However, corticosteroids should be considered for patients with persistent fever despite at least two infusions of IVIG.

Follow-up of patients with treated Kawasaki disease depends on the degree of coronary involvement. In those with no or minimal coronary disease at the time of diagnosis, an echocardiogram 2 weeks and again 6–8 weeks after diagnosis is sufficient. Repeat echocardiography more than 8 weeks after diagnosis in those with no coronary abnormalities is optional. In 2004, the AHA published updated guidelines for the long-term management of Kawasaki disease based on the risk level of the patient. The risk stratification and recommended follow-up can be reviewed in Table 19–16.

CARDIOVASCULAR DISEASES

CARDIOMYOPATHY

The three most common forms of cardiomyopathy in children are (1) dilated, (2) hypertrophic, and (3) restrictive. Two other cardiomyopathies recently classified as distinct entities include arrhythmogenic right ventricular dysplasia (ARVD) and left ventricular noncompaction.

1. Dilated Cardiomyopathy

This most frequent of the childhood cardiomyopathies occurs with an annual incidence of 4–8 cases per 100,000 population in the United States and Europe. Although usually idiopathic, identifiable causes of dilated cardiomyopathy (DCM) include viral myocarditis, untreated tachyarrhythmias, left heart obstructive lesions, congenital abnormalities of the coronary arteries, toxicity (eg, anthracycline), and genetic (eg, dystrophin gene defects, responsible for Duchenne and Becker muscular dystrophies) and metabolic diseases (inborn errors of fatty acid oxidation and mitochondrial oxidative phosphorylation defects). Genetic causes are being discovered at an increasing rate with commercial testing now available for some of the more common genes.

Clinical Findings

A. Signs and Symptoms

As myocardial function fails and the heart dilates, cardiac output falls, and affected children develop decreased exercise tolerance, failure to thrive, diaphoresis, and tachypnea. As the heart continues to deteriorate, congestive signs such as hepatomegaly and rales develop, and a prominent gallop can be appreciated on examination. The initial diagnosis in a previously healthy child can be difficult, as presenting symptoms can resemble a viral respiratory infection, pneumonia, or asthma.

B. Imaging

Chest radiograph shows generalized cardiomegaly with or without pulmonary venous congestion.

C. Electrocardiography

Sinus tachycardia with ST-T segment changes is commonly seen on ECG. The criteria for right and left ventricular hypertrophy may also be met. Evaluation for the presence of supraventricular arrhythmias on ECG is critical, as this is one of the few treatable and reversible causes of DCM in children.

D. Echocardiography

The echocardiogram shows LV and left atrial enlargement with decreased LV shortening fraction and ejection fraction. The calculated end-diastolic and end-systolic dimensions are increased and mitral insufficiency is commonly seen. A careful evaluation for evidence of structural abnormalities (especially coronary artery anomalies) must be performed in infant patients.

E. Other Testing

Cardiac catheterization is useful to evaluate hemodynamic status and coronary artery anatomy. Endomyocardial biopsies can aid in diagnosis. Biopsy specimens may show inflammation consistent with acute myocarditis, abnormal myocyte architecture and myocardial fibrosis. Electron micrographs may reveal evidence of mitochondrial or other metabolic disorders. Polymerase chain reaction (PCR) testing may be performed on biopsied specimens to detect viral genome products in infectious myocarditis. Skeletal muscle biopsy...
CHAPTER 19

may be helpful in patients with evidence of skeletal muscle involvement. Cardiopulmonary stress testing is useful for measuring response to medical therapy and as an objective assessment of the cardiac limitations on exercise.

Treatment & Prognosis

Outpatient management of pediatric DCM usually entails combinations of afterload-reducing agents, digoxin, and diuretics (see section on Heart Failure, earlier). A recently completed multicenter, placebo-controlled, double-blind trial of carvedilol in children with HF will help determine the efficacy of β-blocker therapy as an adjunct in these patients. Aspirin or warfarin may be used to prevent thrombus formation in the dilated and poorly contractile cardiac chambers. Arrhythmias are more common in dilated hearts. Antiarrhythmic agents that do not suppress myocardial contractility, such as amiodarone, are used. Despite widespread use of internal defibrillators in the adult population, the technical difficulty of implanting internal defibrillators and the risk of adverse events (eg, inappropriate discharge) in children limit their use.

Therapy of the underlying cause of cardiomyopathy is always indicated if possible. Unfortunately despite complete evaluation, a diagnosis is discovered in less than 30% of patients with DCM. If medical management is unsuccessful, cardiac transplantation is considered.

2. Hypertrophic Cardiomyopathy

The most common cause of hypertrophic cardiomyopathy (HCM) is familial hypertrophic cardiomyopathy, which is found in 1 in 500 individuals. HCM is the leading cause of sudden cardiac death in young persons. The most common presentation is an older child, adolescent, or adult, although it may occur in neonates. Other causes of HCM in neonates and children are glycogen storage disease, Noonan syndrome, Friedreich ataxia, maternal gestational diabetes, mitochondrial disorders, and other metabolic disorders.

A. Familial Hypertrophic Cardiomyopathy

In the familial form, HCM is most commonly caused by a mutation in one of the several genes that encode proteins of the cardiac sarcomere (B-myosin heavy chain, cardiac tropomyosin T or I, α-tropomyosin, and myosin-binding protein C).

1. Clinical findings—Patients may be asymptomatic despite having significant hypertrophy, or may present with symptoms of inadequate coronary perfusion such as angina, syncope, palpitations, or exercise intolerance. Patients may experience sudden cardiac death as their initial presentation, often precipitated by sporting activities. Although the cardiac examination may be normal on presentation, eventually patients develop a left precordial bulge with a diffuse point of maximal impulse. An LV heave or an S4 gallop may be present. If outflow tract obstruction exists, a systolic ejection murmur will be audible. A murmur may not be audible at rest but may be provoked with exercise or positional maneuvers that decrease left ventricular volume (standing) thereby increasing the outflow tract obstruction.

A. Echocardiography—The diagnosis of HCM is usually made by echocardiography and in most familial cases demonstrates asymmetrical septal hypertrophy. Young patients with metabolic or other nonfamilial causes are more likely to have concentric hypertrophy. Systolic anterior motion of the mitral valve leaflet may occur and contribute to LV outflow tract obstruction. The mitral valve leaflet may become distorted and cause mitral insufficiency over time. LV outflow tract obstruction may be present at rest or provoked with either amyl nitrate or monitored exercise. Systolic function is most often hypercontractile in young children but may deteriorate over time, resulting in poor contractility and LV dilatation. Diastolic function is almost always abnormal.

B. Electrocardiography—The ECG may be normal, but more typically demonstrates deep Q waves in the inferolateral leads (II, III, aVF, V5, and V6) secondary to the increased mass of the hypertrophied septum. ST segment abnormalities may be seen in the same leads. Age-dependent criteria for LVH are often present as are criteria for left atrial enlargement.

C. Other testing—Cardiopulmonary stress testing is valuable to evaluate for provocable LV outflow tract obstruction, ischemia, and arrhythmias, and to determine prognosis. A blunted blood pressure response and ventricular arrhythmias with exercise have both been associated with increased mortality in children. Nuclear stress testing allows for assessment of myocardial perfusion defects. Patients are at risk for myocardial ischemia, possibly as a result of systolic compression of the intramyocardial septal perforators, myocardial bridging of epicardial coronary arteries, or an imbalance of coronary artery supply and demand due to the presence of massive myocardial hypertrophy.

D. Cardiac catheterization—Cardiac catheterization should be performed in patients with HCM who have angina, syncope, resuscitated sudden death, or a worrisome stress test. Hemodynamic findings include elevated left atrial pressure secondary to impaired diastolic filling. If midcavity LV outflow tract obstruction is present, an associated pressure gradient will be evident. Provocation of LV outflow tract obstruction with either rapid atrial pacing or isoproterenol may be sought. Angiography demonstrates a “ballerina slipper” configuration of the LV secondary to the midcavity LV obliteration during systole. The myocardial biopsy specimen demonstrates myofiber disarray.

2. Treatment and prognosis—Treatment varies depending on symptoms and phenotype. Patients are usually restricted from competitive athletics and isometric exercise. Patients with resting or latent LV outflow tract obstruction may be treated with β-blockers, verapamil, or disopyramide with variable success in alleviating obstruction. Patients with severe symptoms despite medical therapy and an LV outflow tract gradient
may require additional intervention. Surgical myectomy with resection of part of the hypertrophied septum has been used with good results. At the time of myectomy, the mitral valve may require repair or replacement in patients with a long history of systolic anterior motion of the mitral valve. Ethanol ablation is being used increasingly in adults with HCM and LV outflow tract obstruction. This procedure involves selective infiltration of ethanol in a coronary septal artery branch to induce a small myocardial infarction. This leads to a reduction in septal size and improvement of obstruction. The long-term effects of this procedure are unknown and it is not currently employed in children. Although dual-chamber pacing has been used in children with good relief of obstruction, larger series demonstrate no significant improvement in obstruction. Risk stratification with respect to sudden death is important in HCM. Internal defibrillators are placed in patients with severe hypertrophy (> 3 cm septal thickness in adults), documented ventricular arrhythmias, resuscitated sudden death, or a strong family history of HCM with associated sudden death.

B. Glycogen Storage Disease of the Heart

There are at least 10 types of glycogen storage disease. The type that primarily involves the heart is Pompe disease (GSD IIa) in which acid maltase, necessary for hydrolysis of the outer branches of glycogen, is absent. There is marked deposition of glycogen within the myocardium. Affected infants are well at birth, but symptoms of growth and developmental delay, feeding problems, and cardiac failure occur by the sixth month of life. Physical examination reveals generalized muscular weakness, a large tongue, and cardiomegaly without significant heart murmurs. Chest radiographs reveal cardiomegaly with or without pulmonary venous congestion. The ECG shows a short PR interval and LVH with ST depression and T-wave inversion over the left precordial leads. Echocardiography shows severe concentric LVH. Children with Pompe disease usually die before age 1 year. Death may be sudden or result from progressive HF.

3. Restrictive Cardiomyopathy

Restrictive cardiomyopathy is a rare entity in the pediatric population, accounting for less than 5% of all cases of cardiomyopathy. The cause is usually idiopathic but can be familial or secondary to an infiltrative process (eg, amyloidosis).

Clinical Findings

Patients present with signs of HF as outlined previously. Physical examination is remarkable for a prominent S4 and jugular venous distention.

A. Electrocardiography

ECG demonstrates marked right and left atrial enlargement with normal ventricular voltages. ST-T-wave abnormalities including a prolonged QTc interval may be present.

B. Echocardiography

The diagnosis is confirmed echocardiographically by the presence of normal sized ventricles with normal systolic function and massively dilated atria. Cardiac MRI is useful in ruling out pericardial abnormalities that can result in similar echocardiographic and clinical findings consistent with restrictive or constrictive pericarditis.

Treatment & Prognosis

Anticongestive therapy is used for symptomatic relief. The high risk of sudden death in restrictive cardiomyopathy and the propensity for rapid progression of pulmonary hypertension warrant close follow-up with early consideration of cardiac transplantation in most patients.

MYOCARDITIS

The most common causes of viral myocarditis are adenovirus, coxsackie A and B viruses, echovirus, cytomegalovirus, parvovirus, and influenza A virus. Human immunodeficiency virus can also cause myocarditis. The ability to identify the pathogen has been enhanced by PCR technology, which replicates identifiable segments of the viral genome from the myocardium of affected children.

Clinical Findings

A. Symptoms and Signs

There are two major clinical patterns. In the first, sudden-onset HF occurs in an infant or child who was relatively healthy 12–24 hours previously. This malignant form of the disease is usually secondary to overwhelming viremia with tissue invasion in multiple organ systems including the heart. In the second pattern, the onset of cardiac symptoms is gradual and there is often a history of upper respiratory tract infection or gastroenteritis in the previous month. This more insidious form may have a late postinfectious or autoimmune component. Acute and chronic presentations occur at any age and with all types of myocarditis.

The signs of HF include pale gray skin; rapid, weak, and thready pulses; and edema of the face and extremities.
Patients are breathless and often orthopneic. The heart sounds may be muffled and distant, an S₃ or S₄ gallop (or both) are common. Murmurs are usually absent, although a murmur of tricuspid or mitral insufficiency may be heard. Moist rales are usually present at both lung bases. The liver is enlarged and frequently tender.

B. Imaging
Generalized cardiomegaly is seen on radiographs along with moderate to marked pulmonary venous congestion.

C. Electrocardiography
The ECG is variable. Classically, there is low-voltage QRS in all frontal and precordial leads with ST-segment depression and inversion of T waves in leads I, III, and aVF (and in the left precordial leads during the acute stage). Dysrhythmias are common, and AV and intraventricular conduction disturbances may be present.

D. Echocardiography
Echocardiography demonstrates four-chamber dilation with poor ventricular function and AV valve regurgitation. A pericardial effusion may be present.

E. Myocardial Biopsy
An endomyocardial biopsy may be helpful in the diagnosis of viral myocarditis. An inflammatory infiltrate with myocyte damage can be seen by hematoxylin and eosin staining. Viral PCR testing of the biopsy specimen may yield a positive result in 30–40% of patients suspected to have myocarditis.

Treatment
The use of digitalis in a rapidly deteriorating child with myocarditis is dangerous and should be undertaken with great caution, as it may cause ventricular dysrhythmias. The inpatient cardiac support measures outlined previously in the section on heart failure are used in the treatment of these patients.

Administration of immunomodulating medications such as corticosteroids for myocarditis is controversial. If the patient’s condition deteriorates despite anticoagulative measures, corticosteroids are commonly used, although conclusive data supporting their effectiveness are lacking. Subsequent to the successful use of IVIG in children with Kawasaki disease, there have been several trials of IVIG in presumed viral myocarditis. The therapeutic value of IVIG remains unconfirmed.

Prognosis
The prognosis of myocarditis is determined by the age at onset and the response to therapy. In patients younger than 6 months or older than 3 years with poor response to therapy, the prognosis is poor. Although complete recovery is possible, many patients recover clinically but have persistent LV dysfunction and a need for ongoing medical therapy for HF. It is possible that subclinical myocarditis in childhood is the pathophysiologic basis for some of the idiopathic dilated cardiomyopathies later in life. Children with myocarditis whose ventricular function fails to return to normal may be candidates for cardiac transplantation.

INFECTIVE ENDOCARDITIS

Positive blood culture.
Intracardiac oscillating mass, abscess, or new valve regurgitation on echocardiogram.
Fever.
Elevated erythrocyte sedimentation rate or C-reactive protein.

General Considerations
Bacterial or fungal infection of the endocardium of the heart is rare and usually occurs in the setting of a preexisting abnormality of the heart or great arteries. It may occur in a normal heart during septicemia or as a consequence of infected indwelling central catheters.

The frequency of infective endocarditis (IE) appears to be increasing for a several reasons: (1) increased survival in children with congenital heart disease, (2) greater use of central venous catheters, and (3) increased use of prosthetic material and valves. Pediatric patients without preexisting heart disease are also at increased risk for IE because of (1) increased survival rates for children with immune deficiencies, (2) long-term use of indwelling lines in ill newborns and patients with chronic diseases, and (3) increased intravenous drug abuse.

Patients at greatest risk are children with unrepaired or palliated cyanotic heart disease (especially in the presence of an aorta to pulmonary shunt), those with implanted prosthetic material, and patients who have had a prior episode of IE. Common organisms causing IE are viridans streptococci.
(30–40% of cases), *Staphylococcus aureus* (25–30%), and fungal agents (about 5%).

#### Clinical Findings

**A. History**

Almost all patients with IE have a history of heart disease. There may or may not be an antecedent infection or surgical procedure (cardiac surgery, tooth extraction, tonsillectomy). Transient bacteremia occurs frequently during normal daily activities such as flossing or brushing teeth, using a toothpick and even when chewing food. Although dental and nonsterile surgical procedures also can result in transient bacteremias these episodes are much less frequent for a given individual. This may be why a clear inciting event is often not identified in association with IE.

**B. Symptoms, Signs, and Laboratory Findings**

Although IE can present in a fulminant fashion with cardiovascular collapse, often it presents in an indolent manner with fever, malaise, and weight loss. Joint pain and vomiting are less common. On physical examination, there may be a new or changing murmur, splenomegaly and hepatomegaly. Classic findings of Osler nodes (tender nodules, usually on the pulp of the fingers), Janeway lesions (nontender hemorrhage macules on palms and soles), splinter hemorrhages, and Roth spots (retinal hemorrhage) are rarely noted. Laboratory findings include positive blood culture, elevated erythrocyte sedimentation rate or C-reactive protein, and hematuria. Transthoracic echocardiography can identify large vegetations in some patients, but transesophageal imaging has better sensitivity and may be necessary if the diagnosis remains in question.

#### Prevention

In 2007, the AHA revised criteria for patients requiring prophylaxis for IE (Table 19–17). Only these high-risk patients require antibiotics before dental work (tooth extraction or cleaning) and procedures involving the respiratory tract or infected skin or musculoskeletal structures. IE prophylaxis is not recommended for gastrointestinal or genitourinary procedures, body piercing, or tattooing.

The following schedule is recommended: under 40 kg, 50 mg/kg of oral amoxicillin; over 40 kg, 2000 mg. This dose is to be given 1 hour prior to the above defined procedures. If the patient is allergic to amoxicillin, an alternative prophylactic antibiotic is used.

#### Treatment

In general appropriate antibiotic therapy should be initiated as soon as IE is suspected. Therapy can be tailored once the pathogen and sensitivities are defined. Vancomycin, with or without gentamicin, for a 6-week course is the most common regimen. If HF occurs and progresses in the face of adequate antibiotic therapy, surgical excision of the infected area and prosthetic valve replacement must be considered.

#### Course & Prognosis

Factors associated with a poor outcome are delayed diagnosis, presence of prosthetic material, perioperative associated IE and *S aureus* infection. Mortality for bacterial endocarditis in children ranges from 10–25% with fungal infections having a much greater mortality at 50% or more.

**PERICARDITIS**

#### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Chest pain made worse by deep inspiration and decreased by leaning forward.
- Fever and tachycardia.
- Shortness of breath.
- Pericardial friction rub.
- ECG with elevated ST segments.

---

**General Considerations**

Pericarditis is an inflammation of the pericardium and is commonly related to an infectious process. The most common cause of pericarditis in children is viral infection (eg, coxsackievirus, mumps, Epstein-Barr, adenovirus, influenza, and HIV). Purulent pericarditis results from bacterial infection (eg, pneumococci, streptococci, staphylococci, *Streptococcus pneumoniae*, *Staphylococcus aureus*).
and *Haemophilus influenzae* and is less common but potentially life-threatening.

In some cases, pericardial disease occurs in association with a generalized process. Associations include rheumatic fever, rheumatoid arthritis, uremia, systemic lupus erythematosus, malignancy, and tuberculosis. Pericarditis after cardiac surgery (postpericardiotomy syndrome) is most commonly seen after surgical closure of an ASD. Postpericardiotomy syndrome appears to be autoimmune in nature with high titers of anti-heart antibody and evidence of fresh or reactivated viral illness. The syndrome is often self-limited and responds well to short courses of aspirin or corticosteroids.

**Clinical Findings**

**A. Symptoms and Signs**

Childhood pericarditis usually presents with sharp stabbing mid chest, shoulder, and neck pain made worse by deep inspiration or coughing, and decreased by sitting up and leaning forward. Shortness of breath and grunting respirations are common. Physical findings depend on the presence of fluid accumulation in the pericardial space (effusion). In the absence of significant accumulation, a characteristic scratchy, high-pitched friction rub may be heard. If the effusion is large, heart sounds are distant and muffled. A friction rub may not be present. In the absence of cardiac tamponade, the peripheral, venous, and arterial pulses are normal.

Cardiac tamponade occurs in association with a large effusion, or one that has rapidly accumulated. Tamponade is characterized by jugular venous distention, tachycardia, hepatomegaly, peripheral edema, and pulesus paradoxus, in which systolic blood pressure drops more than 10 mm Hg during inspiration. Decreased cardiac filling and subsequent decrease in cardiac output result in signs of right heart failure and the potential for cardiovascular collapse.

**B. Imaging**

In pericarditis with a significant pericardial effusion the cardiac silhouette is enlarged. The cardiac silhouette can appear normal if the effusion has developed over an extremely short period of time.

**C. Electrocardiography**

The ST segments are commonly elevated in acute pericarditis. Low voltages or electrical alternans (alteration in QRS amplitude between beats) can be seen with large pericardial effusions.

**D. Echocardiography**

Echocardiography is essential in diagnosis and management of pericarditis. Serial studies allow direct, noninvasive estimate of the volume of fluid and its change over time. Echocardiography also demonstrates cardiac tamponade if there is compression of the atria or respiratory alteration of ventricular inflow.

**Treatment**

Treatment depends on the cause of pericarditis and the size of associated effusion. Viral pericarditis is usually self-limited and symptoms can be improved with nonsteroidal anti-inflammatory therapy. Purulent pericarditis requires immediate evacuation of the fluid and appropriate antibiotic therapy. Cardiac tamponade from any cause must be treated by immediate removal of the fluid, usually via pericardiocentesis. Pericardiocentesis should also be considered if the underlying cause is unclear or identification of the pathogen is necessary for targeted therapy. In the setting of recurrent or persistent effusions, a surgical pericardiectomy or pericardial window may be necessary. Diuretics should be avoided in the patient with cardiac tamponade because they reduce ventricular preload and can exacerbate the degree of cardiac decompensation.

**Prognosis**

Prognosis depends to a great extent on the cause of pericardial disease. Constrictive pericarditis can develop following infectious pericarditis (especially if bacterial) and can be a difficult problem to manage. Cardiac tamponade will result in death unless the fluid is evacuated.

**HYPERTENSION**

Blood pressure should be determined at every pediatric visit beginning at 3 years. Because blood pressure is being more carefully monitored, systemic hypertension has become more widely recognized as a pediatric problem. Pediatric standards for blood pressure have been published. Blood pressures in children must be obtained when the child is relaxed and an appropriate-size cuff must always be used. The widest cuff that fits between the axilla and the antecubital fossa should be used (covers 60–75% of the upper arm). Most children aged 10–11 years need a standard adult cuff (bladder width of 12 cm), and many high school students need a large adult cuff (width of 16 cm) or leg cuff (width of 18 cm). The pressure coinciding with the onset (K1) and the loss (K2) of the Korotkoff sounds determine the systolic and diastolic blood pressure respectively. The 95th percentile value for blood pressure (Table 19–18) is similar for both sexes and all three major ethnic groups. If a properly measured blood pressure exceeds the 95th percentile, the measurement should be repeated several times over a 2- to 4-week interval. If it is elevated persistently, a search for the
CHEST PAIN

Overview

Chest pain is a common pediatric complaint, accounting for 6 in 1000 visits to urban emergency departments and urgent care clinics. Although children with chest pain are commonly referred for cardiac evaluation, chest pain in children is rarely cardiac in origin. Other more likely causes of chest pain in children include reactive airways disease, musculoskeletal pain, esophagitis, gastritis, and functional pain.

Detailed history and physical examination should guide the pediatrician to the appropriate workup of chest pain. Rarely is there a need for laboratory tests or evaluation by a specialist. The duration, location, intensity, frequency, and radiation of the pain should be documented, and possible triggering events preceding the pain should be explored. For instance, chest pain following exertion may lead to a more elaborate evaluation for a cardiac disorder. The timing of the pain in relation to meals may suggest a gastrointestinal cause.

Causes of chest pain in children include reactive airways disease, musculoskeletal pain, esophagitis, gastritis, and functional pain.

CARDIOVASCULAR DISEASES

ATHEROSCLEROSIS & DYSLIPIDEMIAS

Awareness of coronary artery risk factors in general—and atherosclerosis in particular—has risen dramatically in the general population since the mid-1970s. Although coronary artery disease is still the leading cause of death in the United States, the age-adjusted incidence of death from ischemic heart disease has been decreasing as a result of improved diet, decreased smoking, awareness and treatment of hypertension, and an increase in physical activity. The level of serum lipids in childhood usually remains constant through adolescence. Biochemical abnormalities in the lipid profile appearing early in childhood correlate with a higher risk for coronary artery disease in adulthood. Low-density lipoprotein (LDL) is atherogenic, while its counterpart, high-density lipoprotein (HDL) has been identified as an anti-atherogenic factor.

Routine lipid screening of children at age 3 years remains controversial. The National Cholesterol Education Program recommends selective screening in children with high-risk family members, defined as a parent or total cholesterol greater than 240 mg/dL or a parent or grandparent with early-onset cardiovascular disease. When children have LDL levels greater than 130 mg/dL on two successive tests, dietary lifestyle counseling is appropriate. Dietary modification may decrease cholesterol levels by 5–20%. If the patient is unresponsive to diet change and at extreme risk [ie, LDL > 160 mg/dL], HDL less than 35 mg/dL, and a history of cardiovascular disease in a first-degree relative at an age younger than 40 years), drug therapy may be indicated. Cholestyramine, a bile acid binding resin, is rarely used today due to poor adherence. The 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) are more commonly used in the pediatric population. Niacin is useful for treatment of hypertriglyceridemia.

The patient should also be asked about how pain relief is achieved. A social history to reveal psychosocial stressors and cigarette smoke exposure may be revealing. On physical examination, attention must be placed on the vital signs; general appearance of the child; the chest wall musculature; cardiac, pulmonary, and abdominal examination findings; and quality of peripheral pulses. If the pain can be reproduced through direct palpation of the chest wall, it is almost always musculoskeletal in origin.

**Etiology**

Cardiac disease is a rare cause of chest pain, but if misdiagnosed it may be life-threatening. Although myocardial infarction rarely occurs in healthy children, patients with diabetes mellitus, chronic anemia, anomalous left coronary artery, or hypertrophic cardiomyopathy may be at increased risk for ischemia. It is also important to ask the family about a history of Kawasaki disease, as these children are at risk for myocardial infarction secondary to thrombosis of coronary aneurysms. More than 50% of children and adolescents who exhibit sequelae from Kawasaki disease arrive at the emergency department with chest pain.

Young children may mistake palpitations for chest pain. Supraventricular tachycardia (SVT), atrial flutter, premature ventricular contractions (PVCs), or ventricular tachycardia may be associated with chest pain in children. Structural lesions that can cause chest pain include aortic stenosis, pulmonary stenosis, and mitral valve prolapse. Structural cardiac lesions are usually accompanied by significant findings on cardiac examination. Of children with mitral valve prolapse, 30% will complain of chest pain presumably caused by papillary muscle ischemia. Other cardiac lesions causing chest pain include dilated cardiomyopathy, myocarditis, pericarditis, rheumatic carditis, and aortic dissection.

Noncardiac chest pain may be due to a respiratory illness, reactive airway disease, pneumonia, pneumothorax, or pulmonary embolism. Gastrointestinal causes of chest pain include reflux, esophagitis, and foreign body ingestion. The most common cause of chest pain (30% of children) is inflammation of musculoskeletal structures of the chest wall. Costochondritis is caused by inflammation of the costochondral joints and is usually unilateral.

In most cases sophisticated testing is not required. However, if a cardiac origin is suspected, a pediatric cardiologist should be consulted. Evaluation in these instances may include an ECG, chest radiograph, echocardiogram, Holter monitor, or serum troponin levels.

**Cardiac Transplantation**

Cardiac transplantation has become an effective therapeutic modality for infants and children with end-stage cardiac disease. Indications for transplantation include (1) progressive HF despite maximal medical therapy, (2) complex congenital heart diseases that are not amenable to surgical repair or palliation or in instances in which the surgical palliative approach has an equal or higher risk of mortality compared with transplantation, and (3) malignant arrhythmias unresponsive to medical therapy, catheter ablation, or automatic implantable cardioverter-defibrillator. Approximately 300–400 pediatric cardiac transplant procedures are performed annually in the United States. Infant (< 1 year of age) transplants account for 30% of pediatric cardiac transplants. The current estimated half-life for children undergoing cardiac transplantation is approximately 13 years. This is a rapidly evolving field, and the most recent data indicate an optimistic future for the transplant recipient.

Careful evaluation of the recipient and the donor is performed prior to cardiac transplantation. Assessment of the recipient’s pulmonary vascular resistance is critical, as irreversible and severe pulmonary hypertension is a risk factor for post-transplant right heart failure and early death. End-organ function of the recipient may also influence post-transplant outcome and should be evaluated closely. Donor-related factors that can have an impact on outcome include cardiac function, amount of inotropic support needed, active infection (HIV and hepatitis B and C are contraindications to donation), donor size, and ischemic time to transplantation.

**Immunosuppression**

The ideal post-transplant immunosuppressive regimen allows the immune system to continue to recognize and respond to foreign antigens in a productive manner while avoiding graft rejection. Although there are many different regimens, calcineurin inhibitors (eg, cyclosporine and tacrolimus) are the mainstay of maintenance immunosuppression in pediatric heart transplantation. Calcineurin inhibitors may be used in isolation. Double-drug therapy includes the addition of antimetabolite or antiproliferative medications such as azathioprine, mycophenolate mofetil, or sirolimus. Due to the significant adverse side effects of corticosteroids in children, attempts have been made in some centers to discontinue triple-drug therapy that would include steroid use. Growth retardation, susceptibility to infection, impaired wound healing, hypertension, and a cushingoid appearance are some of the consequences of long-term steroid use.

**Graft Rejection**

Despite advances in immunosuppression, graft rejection remains the leading cause of death in the first 3 years after transplantation. The pathophysiologic mechanisms of rejection are not entirely known. T cells are required for rejection, but multiple cell lines and mechanisms are likely involved. Because graft rejection can present in the absence of clinical
symptomatology, monitoring for and diagnosing rejection in a timely fashion can be difficult. Screening regimens include serial physical examinations, electrocardiography, echocardiography, and cardiac catheterization with endomyocardial biopsy.

### Rejection Surveillance

#### A. Symptoms and Signs

Acute graft rejection may not cause symptoms in the early stages. With progression patients may develop tachycardia, tachypnea, rales, a gallop rhythm, or hepatosplenomegaly. Infants and young children may present with irritability, poor feeding, vomiting, or lethargy. The goal is to detect rejection prior to the development of hemodynamic compromise, as there is 50% mortality in the year following an episode of rejection resulting in cardiovascular compromise.

#### B. Imaging

Chest radiographs may show cardiomegaly, pulmonary edema, or pleural effusions.

#### C. Electrocardiography

Abnormalities in conduction can be present, although the most typical finding is reduced QRS voltages. Both atrial and ventricular arrhythmias can occur in rejection.

#### D. Echocardiography

Echocardiography is a noninvasive rejection surveillance tool that is especially useful in infant recipients, but helpful in all ages. Changes in ventricular compliance and function may initially be subtle, but are progressive with increasing duration of the rejection episode. A new pericardial effusion or worsening valvular insufficiency may also indicate rejection.

#### E. Cardiac Catheterization and Endomyocardial Biopsy

Hemodynamic assessment including ventricular filling pressures, cardiac output, and oxygen consumption can be obtained via cardiac catheterization. The endomyocardial biopsy has been considered the gold standard for diagnosing acute graft rejection. However, because not all episodes of symptomatic rejection result in a positive biopsy result, this tool is not universally reliable. The appearance of infiltrating lymphocytes with myocardial damage is the hallmark of graft rejection and is helpful if present.

### Treatment of Graft Rejection

The goal of graft rejection treatment is to reverse the immunologic inflammatory cascade. High-dose corticosteroids are the first line of treatment. Occasionally additional therapy with antithymocyte biologic preparations such as antithymocyte globulin or OKT-3 (a murine monoclonal antibody to the CD3 T-lymphocyte epitope) is needed to reverse rejection. Most rejection episodes can be treated effectively if diagnosed promptly. Usually graft function returns to its baseline state, although severe rejection episodes can result in graft loss and patient death even with optimal therapy.

### Course & Prognosis

The course of cardiac transplantation in pediatric patients is usually quite good. The risk of infection is low after the immediate post-transplant period in spite of chronic immunosuppression. Cytomegalovirus is the most common pathogen responsible for infection-related morbidity and mortality in heart transplant recipients. Most children tolerate environmental pathogens well. Nonadherence with lifetime immunosuppression is of great concern especially in adolescent patients. Several recent studies have identified nonadherence as the leading cause of late death. Post-transplant lymphoproliferative disorder, a syndrome related to Epstein-Barr virus infection, can result in a Burkitt-like lymphoma that usually responds to a reduction in immunosuppression, but occasionally must be treated with chemotherapy. The overwhelming majority of children are not physically limited and do not require restrictions related to the cardiovascular system.

The greatest long-term concern after heart transplantation is related to cardiac allograft vasculopathy. Cardiac allograft vasculopathy results from concentric intimal proliferation of the coronary arteries that can ultimately result in complete luminal occlusion. These lesions are diffuse and often involve distal vessels and thus are usually not amenable to bypass grafting, angioplasty, or stent placement. Overall, despite the concerns of immunosuppression, the risk of late rejection, and coronary disease, the majority of pediatric patients enjoy a good quality of life with survival rates that are improving. Currently, 10-year survival is 80% for infant recipients and 70% overall for all pediatric recipients. Newer, more specific, and more effective immunosuppressive agents are currently being tried in clinical studies or are being evaluated in preclinical studies, making the future almost certainly better for children after cardiac transplantation. Donor availability remains a major limitation to the expansion of indications for cardiac transplantation.
PRIMARY PULMONARY HYPERTENSION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Often subtle with symptoms of dyspnea, fatigue, chest pain, and syncope.
- Loud pulmonary component of \( S_2 \); ECG with RVH.
- Implies exclusion of secondary causes of pulmonary hypertension.
- Rare, progressive, and often fatal disease without treatment.

General Considerations

Unexplained or primary pulmonary hypertension (PPH) in children is a rare disease with an estimated overall incidence of 1–2 persons per million worldwide. Pulmonary hypertension is defined as a mean pulmonary pressure greater than 25 mm Hg at rest or greater than 30 mm Hg during exercise. PPH is a diagnosis made after exclusion of all other causes of pulmonary hypertension. Secondary pulmonary hypertension is most commonly associated with congenital heart disease, pulmonary parenchymal disease, causes of chronic hypoxia (upper airway obstruction), thrombosis, liver disease, hemoglobinopathies and collagen vascular disease. PPH is difficult to diagnose in the early stages because of its subtle manifestations. Most patients with PPH are young adult women, although the sex incidence is equal in children. As recently as 1991, the diagnosis of PPH in individuals younger than 16 years of age carried a median survival of only 10 months. Fortunately, survival is improving with the advent of new therapies. Familial PPH occurs in 6–12% of affected individuals. When a clear familial association is known, the disease shows evidence of genetic anticipation, presenting at younger ages in subsequent generations.

Clinical Findings

A. Symptoms and Signs

The clinical picture varies with the severity of pulmonary hypertension, and usually early symptoms are subtle, delaying the diagnosis. Initial symptoms may be dyspnea, palpitations, or chest pain, often brought on by strenuous exercise or competitive sports. Syncope may be the first symptom, which usually implies severe disease. As the disease progresses, patients have signs of low cardiac output and right heart failure. Right heart failure may be manifested by increasing hepatomegaly, peripheral edema, and an \( S_2 \) gallop on examination. Murmurs of pulmonary regurgitation and tricuspid regurgitation may be present, and the pulmonary component of \( S_2 \) is usually pronounced.

B. Imaging

The chest radiograph most often reveals a prominent main pulmonary artery, and the RV may be enlarged. The peripheral pulmonary vascular markings may be normal or diminished. However, in 6% of patients with confirmed PPH, the chest radiograph is normal.

C. Electrocardiography

The ECG usually shows right ventricular hypertrophy with an upright T wave in \( V_1 \) (from age 7 days to 7 years) or a qR complex in lead \( V_1 \) or \( V_3 \). Also present may be evidence of right axis deviation and right atrial enlargement.

D. Echocardiography

The echocardiogram is an essential tool for excluding other congenital heart diseases. It frequently shows RVH and dilatation. In the absence of other structural disease, any tricuspid and pulmonary insufficiency jets can be used to estimate pulmonary artery systolic and diastolic pressures, respectively. Other echocardiographic modalities such as myocardial performance index and input vascular impedance are in the early stages of use in evaluation of pulmonary hypertension.

E. Cardiac Catheterization and Angiocardiography

Cardiac catheterization is the best method of diagnosing PPH. As an invasive test, it carries with it associated risks and should be performed with caution. The procedure is performed to rule out cardiac causes of pulmonary hypertension, determine the severity of disease, and define treatment strategies. The reactivity of the pulmonary vascular bed to short-acting vasodilator agents (oxygen, nitric oxide, or prostacyclin) can be assessed and used to determine treatment options. Angiography may show a decrease in the number of small pulmonary arteries with tortuous vessels.

F. Other Evaluation Modalities

Cardiac MRI is used in some patients to measure heart function and blood flow. Cardiopulmonary exercise testing using cycle ergometry correlates with disease severity. More simply, a 6-minute walk test, in which distance walked and perceived level of exertion are measured, has a strong independent association with mortality in late disease.

Treatment

The goal of therapy is to reduce pulmonary artery pressure and increase cardiac output. Cardiac catheterization data are
**Sinus Bradycardia**

Depending on age, sinus bradycardia is defined as either (1) a heart rate below the normal limit for age (neonates to 6 years, 60 beats/min; 7–11 years, 45 beats/min; older than 12 years, 40 beats/min) or (2) a heart rate inappropriately slow for the functional status of the patient (chronotropic incompetence). In critically ill patients, common causes of sinus bradycardia include hypoxia, central nervous system damage, eating disorders, and medication side effects. Only symptomatic bradycardia (syncope, low cardiac output, or exercise intolerance) requires treatment (atropine, isoproterenol, or cardiac pacing).

**Sinus Tachycardia**

The heart rate normally accelerates in response to stress (e.g., fever, hypovolemia, anemia, or HF). Although sinus tachycardia in the normal heart is well tolerated, symptomatic tachycardia with decreased cardiac output warrants evaluation for structural heart disease or true tachyarrhythmias. Treatment may be indicated for correction of the underlying cause of sinus tachycardia (e.g., transfusion for anemia or correction of hypovolemia or fever).

**PREMATURE ATRIAL CONTRACTIONS**

Premature atrial contractions are triggered by an ectopic focus in the atrium. They are one of the most common premature beats occurring in pediatric patients, particularly during the fetal and newborn periods. They may be conducted (followed by a QRS) or nonconducted (not followed by a QRS, as the beat has occurred so early that the AV node is still refractory) (Figure 19-4). A less-than-compensatory pause usually occurs until the next normal sinus beat. Depending on the location of the ectopic focus of the premature contraction, the P-wave morphology may be normal or abnormal. As an isolated finding, premature atrial contractions are benign and require no treatment. They need to be treated with antiarrhythmic agents only when they trigger tachyarrhythmias or produce bradycardia secondary to nonconduction.

**PREMATURE JUNCTIONAL CONTRACTIONS**

Premature junctional contractions arise in the AV node or the bundle of His. They usually induce a normal QRS complex with no preceding P wave. When conducted aberrantly to the ventricles, they cannot be distinguished from PVCs except by invasive electrophysiologic study. Premature junctional contractions are usually benign and require no specific therapy.

**PREMATURE VENTRICULAR CONTRACTIONS**

PVCs may originate in either ventricle and are characterized by an abnormal QRS of more than 80 ms duration in

**DISORDERS OF RATE & RHYTHM**

As more children are surviving cardiac surgery and living with chronically altered hemodynamics there has been an increase in the incidence of arrhythmias in the pediatric population.

The introduction of invasive electrophysiology with recordings from the endocardium has greatly improved understanding of the conduction system. Cardiac ablation techniques offer some children with arrhythmias a cure rather than lifelong antiarrhythmia treatment.

**Sinus Arrhythmia**

Phasic variation in the heart rate (sinus arrhythmia) is normal. Typically, the sinus rate varies with the respiratory cycle, whereas P-QRS-T intervals remain stable. Marked sinus arrhythmia is defined as more than 100% variation in heart rate. It may occur in association with respiratory distress or increased intracranial pressure, or it may be present in normal children. In isolation, it never requires treatment; however, it may be associated with sinus node dysfunction or autonomic nervous system dysfunction.

**Atrial Septostomy**

Is indicated in some patients with refractory pulmonary hypertension. Cardiac output falls as pulmonary vascular resistance rises, so an interatrial shunt can preserve left heart output, albeit with deoxygenated blood. Lung transplantation should be considered in patients with intractable pulmonary hypertension and in those with associated anatomic lesions that contribute to high pulmonary arterial pressure, like pulmonary vein stenosis. Heart-lung transplant procedures appear to have survival benefits over isolated lung transplantation in patients with pulmonary hypertension.

Although survival is less than 10 months in children with untreated pulmonary hypertension, recent studies have shown improved survival rates of more than 95% at 5 years with calcium channel blockade, and more than 80% at 5 years in children requiring epoprostenol.

newborns and more than 120 ms in adolescents and adults (Figure 19–5). PVCs originating from a single ectopic focus all have the same configuration; those of multifocal origin show varying configurations. The consecutive occurrence of two PVCs is referred to as a ventricular couplet and of three or more as ventricular tachycardia.

Most unifocal PVCs in otherwise normal patients are benign. The significance of PVCs can be confirmed by having the patient exercise. As the heart rate increases, benign PVCs usually disappear. If exercise results in an increase or coupling of contractions, underlying disease may be present. Multifocal PVCs are always abnormal and may be more dangerous. They may be associated with drug overdose (tricyclic antidepressants or digoxin toxicity), electrolyte imbalance, myocarditis, or hypoxia. Treatment is directed at correcting the underlying disorder.

**SINUS NODE DYSFUNCTION**

Sinus node dysfunction, or sick sinus syndrome, is a clinical syndrome of inappropriate sinus nodal function and rate. The abnormality may be a true anatomic defect of the sinus node or its surrounding tissue, or it may be an abnormality of autonomic input. It is defined as one or more of the following:

1. Sinus bradycardia
2. Marked sinus arrhythmia
3. Chronotropic incompetence
4. Sinus pause or arrest
5. Sinoatrial exit block
6. Combined bradyarrhythmias and tachyarrhythmias
7. Sinus node reentry
8. Atrial muscle reentry tachycardia

It is usually associated with postoperative repair of congenital heart disease (most commonly the Mustard or Senning repair for complete transposition of the great arteries or the Fontan procedure), but it is also seen in unoperated congenital heart disease, in acquired heart diseases, and in normal hearts. In some cases the disorder is inherited. Symptoms usually manifest between ages 2 and 17 years and consist of episodes of syncope, presyncope, or disorientation. Some patients may experience palpitations, pallor, or exercise intolerance.
The evaluation of sinus node dysfunction involves both surface ECG and invasive electrophysiologic testing. Exercise testing and ambulatory monitoring help define any arrhythmias and correlate rhythm changes with symptoms.

Treatment for sinus node dysfunction is indicated only in symptomatic patients. Asymptomatic patients can be observed for the onset of exercise intolerance or syncope because there is little chance of sudden death prior to the onset of such symptoms. Bradyarrhythmias are treated with vagolytic (atropine) or adrenergic (aminophylline) agents or permanent cardiac pacemakers. Antiarrhythmic treatment of tachyarrhythmias often produces or enhances bradycardia, thus requiring permanent cardiac pacing. A pacemaker is inserted prophylactically prior to the initiation of antiarrhythmic medications.

The prognosis is excellent when appropriate treatment is provided, with morbidity and mortality rates nearly equal to those of the underlying heart disease. In severe untreated cases, sinus node dysfunction may become chronic and may lead to sudden death.

SUPRAVENTRICULAR TACHYCARDIA

SVT, also known as paroxysmal SVT or paroxysmal atrial tachycardia, is defined as an abnormal arrhythmia mechanism arising above or within the bundle of His. The mode of presentation depends on the heart rate, the presence of underlying cardiac structural or functional abnormalities, coexisting illness, and patient age. Tachycardia may be poorly tolerated in a child with preexisting HF or an underlying systemic disease such as anemia or sepsis. It may go unnoticed in an otherwise healthy child. Incessant tachycardia in an otherwise healthy individual, even if fairly slow (120–150 beats/min), may cause myocardial dysfunction and HF if left untreated. The mechanisms of tachycardia are divided into three groups: reentry, enhanced automaticity, and triggered dysrhythmias.

Reentry is conduction through two or more pathways, creating a sustained repetitive circular loop. The circuit can be confined to the atrium (intra-atrial reentry, a form of atrial flutter) (Figure 19–6). It may be confined within the AV node (AV nodal reentrant tachycardia), or it may encompass an accessory connection between atria and ventricle (atrioventricular tachycardia). The arrhythmia circuit includes conduction through the normal pathway (the AV node) as well as the accessory AV connection. If during tachycardia the electrical impulse travels antegrade (from atria to ventricles) through the AV node and retrograde (from ventricle to atria) back up the accessory pathway, orthodromic reciprocating tachycardia is present. If instead the impulse travels antegrade through the accessory pathway and retrograde up through the AV node, antidromic reciprocating tachycardia is present.

Wolff-Parkinson-White (WPW) syndrome is a subclass of reentrant tachycardia in which, during sinus rhythm, the impulse travels antegrade down the accessory connection, bypassing the AV node and creating ventricular preexcitation (early eccentric activation of the ventricle with a short PR interval and slurred upstroke of the QRS, a delta wave) (Figure 19–7). Reentrant tachycardia represents approximately 80% of pediatric arrhythmias, has a wide range of rates, and may or may not demonstrate P waves. Reentrant tachycardia initiates and terminates abruptly. Most patients
with WPW have otherwise structurally normal hearts. However, WPW has been noted to occur with increased frequency in association with the following congenital cardiac lesions: tricuspid atresia, Ebstein anomaly of the tricuspid valve, hypertrophic cardiomyopathy, and congenitally corrected transposition of the great arteries (ccTGA).

Enhanced automaticity (also known as automatic or ectopic tachycardia) is created when a focus of cardiac tissue develops an abnormally fast spontaneous rate of depolarization. These arrhythmias represent approximately 20% of childhood arrhythmias and are usually under autonomic influence. ECG demonstrates a normal QRS complex preceded by an abnormal P wave (Figure 19–8). Junctional ectopic tachycardia does not have a P wave preceding the QRS waves and may be associated with AV dissociation or 1:1 retrograde conduction. Ectopic tachycardias demonstrate a gradual onset and offset and may be paroxysmal or incessant. When they are incessant, they are usually associated with HF and a clinical picture of dilated cardiomyopathy.

Triggered dysrhythmia is extremely rare. It is caused by afterdepolarizations. These tachycardias are usually associated with diseased atrial myocardium, are triggered by premature atrial contractions or sinus tachycardia, initiate and terminate abruptly, and mimic intra-atrial reentry (atrial flutter). However, they can be distinguished from atrial flutter: they terminate with the administration of adenosine, whereas atrial flutter does not (see later section on Atrial Flutter and Fibrillation).

**Clinical Findings**

**A. Symptoms and Signs**

Presentation varies with age. Infants tend to turn pale and mottled with onset of tachycardia and may become irritable. With long duration of tachycardia, symptoms of HF develop. Heart rates range from 240–300 beats/min. Older children complain of dizziness, palpitations, fatigue, and chest pain. Heart rates range from 240 beats/min in the younger child to 150–180 beats/min in the teenager. HF is less common in children than in infants. Tachycardia may be associated with either congenital heart defects or acquired conditions such as cardiomyopathies and myocarditis.

**B. Imaging**

Chest radiographs are normal during the early course of tachycardia. If HF is present, the heart is enlarged and pulmonary venous congestion is evident.

**C. Electrocardiography**

ECG is the most important tool in the diagnosis of SVT.

1. The heart rate is rapid and out of proportion to the patient’s physical status (ie, a rate of 140 beats/min with an abnormal P wave while quiet and asleep).
2. The rhythm is extremely regular. There is little variation in the rate throughout the entire tracing.
3. P waves may or may not be present. If they are present, the PR interval and appearance do not vary. P waves may be difficult to find because they are superimposed on the preceding T wave. Furthermore, if the abnormal focus is located within the AV node, the P waves will not be seen.

4. The QRS complex is usually the same as during normal sinus rhythm. However, the QRS complex is occasionally widened (SVT with aberrant ventricular conduction), in which case the condition may be difficult to differentiate from ventricular tachycardia.

Treatment

A. Acute Treatment

During the initial episodes of SVT, patients require close monitoring. Correction of acidosis and electrolyte abnormalities is also indicated.

1. Vagal maneuvers—The “diving reflex” produced by placing an ice bag on the nasal bridge for 20 seconds (for infants) or by immersing the face in ice water (for children or adolescents) will increase parasympathetic tone and terminate some tachycardias. The Valsalva maneuver, which can be performed by older compliant children, may also terminate SVT.

2. Adenosine—Adenosine transiently blocks AV conduction and terminates tachycardias that incorporate the AV node.

Adenosine does not convert tachycardias whose mechanism is confined to the atria (atrial ectopic tachycardia or intra-atrial reentry). However, it serves as a diagnostic tool in these arrhythmias by demonstrating continuation of the atrial tachycardia during AV block, implying that AV node conduction is not a crucial element of the tachycardia circuit. The dose is 50–250 mcg/kg by rapid intravenous bolus. It is antagonized by aminophylline and should be used with caution in patients with sinus node dysfunction or asthma.

3. Transesophageal atrial pacing—Atrial overdrive pacing and termination can be performed from a bipolar electrode-tipped catheter positioned in the esophagus adjacent to the left atrium. Overdrive pacing at rates approximately 30% faster than the tachycardia rate will interrupt the tachycardia circuit and restore sinus rhythm.

4. Direct current cardioversion—Direct current cardioversion (0.5–2 synchronized J/kg) should be used immediately when a patient presents in cardiovascular collapse.

B. Chronic Treatment

1. Digitalis—Digoxin is still used for long-term treatment and maintenance of sinus rhythm. The doses used are the same as those for HF. Conversion should be accomplished within 8–12 hours. In some patients, digoxin accelerates conduction over an accessory pathway. In such children, digitalis products are contraindicated. Patients with an accessory pathway (eg, those with WPW syndrome) often have primary atrial tachycardias (atrial flutter or fibrillation or atrial ectopic tachycardias), and with enhanced conductin in the accessory pathway these primary atrial tachycar-
dias can transmit to the ventricles, causing ventricular fibrillation. Therefore, an evaluation of the effect of digoxin on the accessory pathway should be performed in the electrophysiology lab before chronic digoxin use in patients with WPW syndrome.

2. β-Adrenergic blocking agents—Propranolol decreases sinus heart rate and AV nodal conduction. It is effective in the treatment of both reentrant and ectopic arrhythmias in doses ranging from 1–4 mg/kg/d. Long-acting β-blockers, such as atenolol and nadolol, are used because they have fewer central nervous system side effects than propranolol and may be given only once or twice a day.

3. Calcium channel antagonists—Verapamil and other calcium channel blockers markedly prolong conduction through the AV node and are effective in interrupting and preventing reentrant tachycardias that incorporate the AV node. They are ineffective in terminating atrial tachycardias but may be useful in controlling the ventricular response by producing AV blockade. Verapamil comes in short- and long-acting preparations; the dose is 3–5 mg/kg/d. It may cause myocardial dysfunction and is contraindicated in infants.

4. Other drugs—Recently introduced antiarrhythmic medications (eg, flecainide, propafenone, sotalol, and amiodarone) have increased pharmacologic actions and are extremely effective. However, these drugs also have serious side effects, including proarrhythmia (production of arrhythmias) and sudden death, and should be used only under the direction of a pediatric cardiologist.

5. Radiofrequency ablation—This is a nonsurgical transvascular catheter technique that desiccates an arrhythmia focus or accessory pathway and permanently cures an arrhythmia. The success rate is approximately 90%, with a recurrence rate of 10%. The risk of developing complete heart block is approximately 2–5% when applying burns in the vicinity of the AV node/His bundle. The procedure can be performed in infants or adults. In children younger than age 4 years, the risks are higher, and the procedure should be reserved for those whose arrhythmias are refractory to medical management. In well-tolerated SVTs that respond to vagal maneuvers, no further treatment is necessary. However, the high success rate, low complica- tion and recurrence rates, and the elimination of the need for chronic antiarrhythmic medications have made radiofrequency ablation the primary treatment option in most pediatric cardiovascu- lar centers.

**Prognosis**

SVT has an excellent prognosis. When it occurs in early infancy, 90% will respond to initial treatment. Approximately 30% will recur at an average age of 8 years.

**Atrial Flutter & Fibrillation**

Atrial flutter and fibrillation are rare in children and are most often associated with organic heart disease—particularly postoperative congenital heart disease and sinus node dysfunction. Atrial flutter can occur in infancy and can mimic SVT. The atrial rate is usually more than 240 beats/min and often more than 300 beats/min. The ventricular rate depends on the rate of AV conduction and is usually slower than the atrial rate.

**Treatment & Prognosis**

Transesophageal atrial pacing is the treatment of choice to terminate atrial flutter. When it is not successful, antiar- rhythmic medications (eg, digoxin, sotalol, and amiodarone) may succeed; however, direct current cardioversion is frequently necessary.

The prognosis in neonates without structural heart disease is excellent, and after conversion these patients may need no further treatment.

**Postoperative Incisional Intra-Atrial Reentry**

Improved surgical survival for patients with congenital heart disease has created a new, increasingly prevalent, chronic arrhythmia: incisional intra-atrial reentry, or postoperative atrial flutter. In these tachycardias, electrically isolated corridors of atrial myocardium (eg, the tricuspid valve–inferior vena cava isthmus, or the region between an atrial incision and the crista terminalis) act as pathways for sustained reentrant circuits of electrical activity. These tachycardias are chronic, medically refractory, and clinically incapacitating. Electromagnetic mapping permits precise localization of these corridors. Long linear radiofrequency or surgical lesions are then used to interrupt the reentrant circuits.

**Ventricular Tachycardia**

Ventricular tachycardia is uncommon in childhood (Figure 19–9). It is usually associated with underlying abnormalities of the myocardium (myocarditis, cardiomyopathy, myocardial tumors, or postoperative congenital heart disease) or toxicity (hypoxia, electrolyte imbalance, or drug toxicity). Sustained tachycardia is generally an unstable
CARDIOVASCULAR DISEASES

situation, and if left untreated will usually degenerate into ventricular fibrillation.

Accelerated idioventricular rhythm is a sustained ventricular tachycardia occurring in neonates with normal hearts. The rate is within 10% of the preceding sinus rate, and it is a self-limiting arrhythmia that requires no treatment.

Acute termination of ventricular tachycardia involves restoration of the normal myocardium when possible (correction of electrolyte imbalance, drug toxicity, and so on) and direct current cardioversion (1–4 J/kg), cardioversion with lidocaine (1 mg/kg), or both. Chronic suppression of ventricular arrhythmias with antiarrhythmic drugs has many side effects (including proarrhythmia and death), and it must be initiated in the hospital under the direction of a pediatric cardiologist.

LONG QT SYNDROME

The congenital long QT syndromes (types 1–6) in children are arrhythmic disorders in which ventricular repolarization is irregular and prolonged (QTc > 0.44 second, or 0.46 second in postpubertal females). Some myocardial ion channelopathies predispose patients to torsade de pointes (multifocal ventricular tachycardia) and manifest as syncope, seizures, or sudden death, often in response to exercise. If untreated, they account for a very high mortality rate (5% per year). They are inherited genetically in an autosomal dominant or recessive pattern (the latter being associated with congenital deafness, the Jervell and Lange-Nielsen syndrome) or they may arise spontaneously. Treatment with β-blockade and exercise limitation is only partially successful. In recurrent, medically refractory cases, implantable cardioverter defibrillators are necessary to prevent sudden death. Congenital long QT syndrome has now been demonstrated to be one of the causes of sudden infant death syndrome.

Acquired long QT syndrome—resulting from altered ventricular repolarization secondary to myocardial toxins, ischemia, or inflammation—also predisposes a patient to ventricular arrhythmias. Numerous medications as outlined previously can also cause QT prolongation. ECGs are recommended before therapy (for a baseline measurement) and after steady state is achieved.

SUDDEN DEATH

Hypertrophic cardiomyopathy (the most common cause of sudden death in young athletes) and other cardiomyopathies (dilated cardiomyopathies, restrictive cardiomyopathy, or arrhythmogenic RV dysplasia) may be hereditary.
and should be looked for in patients with resuscitated cardiac arrest or family members of those who have died suddenly. Congenital structural anomalies of the coronary arteries are the second most common cause of sudden death in young athletes. These anomalies are not hereditary. The coronary arteries need to be evaluated in survivors of sudden death events. Arrhythmias in patients with postoperative congenital heart disease are important causes of morbidity and mortality and may present as sudden death events. All survivors of cardiac arrest require thorough evaluation for arrhythmias, including invasive electrophysiology. Episodes of seizures, syncope, and presyncope in patients with congenital heart disease should be evaluated for the possibilities of arrhythmias, and they may also require thorough electrophysiologic evaluation and treatment.

When a child dies suddenly and unexpectedly, or is resuscitated from cardiac arrest that had no apparent cause, it is necessary to conduct a detailed family history looking for seizures, syncope, or early sudden death. Family members should be examined with an arrhythmia screen, physical examination, ECG, and echocardiography to detect arrhythmias or cardiomyopathies.

HEART BLOCK

1. First-Degree Heart Block
First-degree heart block is an ECG diagnosis of prolongation of the PR interval. The block does not in itself cause problems. It may be associated with structural congenital heart defects, namely AV septal defects and ccTGA, and with diseases such as rheumatic carditis. The PR interval is prolonged in patients receiving digoxin therapy.

2. Second-Degree Heart Block
Mobitz type I (Wenckebach) heart block is recognized by progressive prolongation of the PR interval until there is no QRS following a P wave (Figure 19–10). Mobitz type I heart block occurs in normal hearts at rest and is usually benign. In Mobitz type II heart block, there is no progressive lengthening of the PR interval before the dropped beat (Figure 19–11). Mobitz type II heart block is frequently associated with organic heart disease, and a complete evaluation is necessary.

3. Complete Heart Block
In complete heart block, the atria and ventricles beat independently. Ventricular rates can range from 40–80 beats/min, whereas atrial rates are faster (Figure 19–12).
Congenital complete heart block, the most common form of complete heart block, has a very high association with maternal systemic lupus erythematosus antibodies. Serologic screening should be performed in the mother of an infant with complete heart block, even if she has no symptoms of collagen vascular disease. Congenital complete heart block is also associated with congenitally corrected transposition of the great vessels and AV septal defect. Acquired complete heart block may be secondary to acute myocarditis, drug toxicity, electrolyte imbalance, hypoxia, and cardiac surgery.

Clinical Findings
Prenatal bradycardia is frequently noted in infants with congenital complete heart block, and emergent delivery is required if hydrops fetalis develops. Postnatal adaptation largely depends on the heart rate; infants with heart rates less than 55 beats/min are at significantly greater risk for low
cardiac output, HF, and death. Wide QRS complexes and a rapid atrial rate are also poor prognostic signs. Most patients have an innocent flow murmur from increased stroke volume. In symptomatic patients, the heart can be quite enlarged, and pulmonary edema may be present. In older patients, syncope can be the presenting symptom, or heart block may be found unexpectedly on routine physical examination. Complete cardiac evaluation, including echocardiography and Holter monitoring, is necessary to assess the patient for ventricular dysfunction and to relate any symptoms to concurrent arrhythmias.

**Treatment**

In patients thought to be at risk for syncope, HF, or sudden death, the treatment of choice for complete heart block is insertion of a permanent pacemaker. Until permanent pacing can be instituted, patients can be assisted temporarily by infusions of isoproterenol or by temporary transcutaneous pacemakers.

▲ Figure 19-11. Lead III rhythm strip with Mobitz type II second-degree heart block. There is a consistent PR interval with occasional loss of AV conduction (arrow).

▲ Figure 19-12. Twelve-lead ECG and lead II rhythm strip of complete heart block. The atrial rate is 150 beats/min, and the ventricular rate is 60 beats/min.
SYNCOPE (FAINTING)

Syncope is a sudden transient loss of consciousness that resolves spontaneously. The common form of syncope (simple fainting) occurs in 15% of children and is a disorder of control of heart rate and blood pressure by the autonomic nervous system that causes hypotension or bradycardia. It is often associated with rapid rising and postural hypotension, prolonged standing, or hypovolemia. Patients exhibit vagal symptoms such as pallor, nausea, or diaphoresis. Syncope, also known as autonomic dysfunction, can be evaluated with head-up tilt table testing. The patient is placed supine on a tilt table, and then—under constant heart rate and blood pressure monitoring—is tilted to the upright position. If symptoms develop, they can be classified as vasodepressor (hypotension), cardioinhibitory (bradycardia), or mixed.

Syncope is usually self-limited (lasting approximately 6 months to 2 years) and can be controlled with dietary salt and volume loading to prevent hypovolemia. In refractory cases, medications to manipulate the autonomic nervous system have been useful. Fludrocortisone (0.1 mg/kg/d) is a mineralocorticoid that causes renal salt resorption and thus increases intravascular volume. β-Blockade (atenolol, 0.5–2.0 mg/kg/d) can inhibit the catecholamine surge and help prevent the rebound bradycardia and hypotension. Vagolytic agents (disopyramide, 2.5 mg/kg four times daily) help control hypervagotonia, and the selective serotonin reuptake inhibitors have also been effective in alleviating symptoms. Syncope that occurs during exercise or stress or is associated with a positive family history is a warning sign that a serious underlying dysrhythmia may be present, calling for further investigation.

Recurrent post-prandial spitting and vomiting in healthy infants that resolves spontaneously.

Heartburn and regurgitation in older children.

Chronic complications—esophagitis, stricture, anemia, and Barrett esophagus.

Diagnosis is clinical in infancy with upper gastrointestinal (GI) radiograph and upper endoscopy to rule out other GI disease.

Clinical Findings

A. Infants with Reflux

Gastroesophageal (GE) reflux is common in young infants. Frequent post-prandial regurgitation, ranging from effortless to forceful, is the most common infant symptom. Infant reflux is usually benign but in rare cases causes failure to thrive, food refusal, colic, rumination, and neck contortions (Sandifer syndrome). Apneic spells in young infants, especially occurring with position change after feeding, may be caused by reflux. GE reflux is common in neurologically impaired infants.

Reflux of gastric contents into the esophagus occurs during spontaneous relaxations of the lower esophageal sphincter that are unaccompanied by swallowing. Low pressures in the lower esophageal sphincter or developmental immaturity of the sphincter are not causes of GE reflux in infants. Normal factors promoting reflux in infants are their small stomach capacity, frequent large-volume feedings, short esophageal length, supine positioning, and slow swallowing response to the flow of refluxed material up the esophagus. Infants’ individual responses to the stimulus of reflux, particularly the maturity of their self-settling skills, are important factors determining the severity of reflux-related symptoms.

An important differential point in evaluating infants with GE reflux is whether the vomited material contains bile. Bile-stained emesis in an infant requires immediate evaluation as it may be a symptom of intestinal obstruction (malrotation with volvulus, intussusception).

B. Older Children with Reflux

GE reflux disease (GERD) is diagnosed clinically in older children when reflux causes persistent symptoms with or without inflammation of the esophagus. Older children with GERD have less frequent vomiting than infants, and more often complain of adult-type symptoms of regurgitation into the mouth, heartburn, and dysphagia. Esophagitis occurs in children with GERD and requires endoscopic evaluation. Children with asthma, cystic fibrosis, developmental handicaps, hiatal hernia, and repaired tracheoesophageal fistula are at increased risk of GERD.

C. Diagnostic Studies

In thriving infants, GE reflux is a clinical diagnosis. An upper GI series rules out anatomic causes of vomiting but is not an accurate test for GE reflux because of a 30% false-positive rate. In older children with heartburn, a trial of acid-suppressing medication may be both diagnostic and therapeutic. Persistent symptoms should be investigated by upper GI radiographs and endoscopy to rule out other organic causes. pH probe or esophageal impedance studies may be helpful in recognizing an association between episodic or unusual symptoms and reflux events. pH studies quantify the number and duration of acid reflux events. Esophageal intraluminal impedance monitoring is a pH-independent method of detecting fluid movements in the esophagus. These studies have shown that episodes of nonacid reflux occur as frequently as acid reflux.
episodes and that treatment with acid-suppressing medications changes the proportions of acid versus nonacid events, not the total number of events. Esophagoscopy is not diagnostic of reflux, but esophagitis can be identified.

Treatment & Prognosis

Reflux resolves spontaneously in 85% of affected infants by 12 months of age, coincident with assumption of erect posture and initiation of solid feedings. Until then, regurgitation volume may be reduced by offering small feedings at frequent intervals and by thickening feedings with rice cereal (2–3 tsp/oz of formula). Prethickened “anti-reflux” formulas are available. Histamine-2 (H2)–receptor antagonists (ranitidine, 5 mg/kg/d in two doses) or proton pump inhibitors (omeprazole, 0.5–1.0 mg/kg/d in one dose) do not reduce the frequency of reflux but may reduce pain behavior. Prokinetic agents such as metoclopramide hasten gastric emptying and improve esophageal motor function, but studies have not shown efficacy in controlling symptoms. A short trial of protein hydrolysate formula (hypoallergenic) sometimes controls emesis and pain behavior in infants with protein sensitivity. Special formulas and acid suppression agents are costly and should be discontinued if there is no improvement of symptoms in 1 week.

Spontaneous resolution is less likely in older children with GERD. Episodic heartburn pain may be controlled with intermittent use of acid blockers. Patients with more severe heartburn or esophagitis require regular acid suppression. Untreated esophagitis may cause esophageal stricture and anemia from blood loss. Barrett esophagus, a precancerous condition, is rare in childhood but can occur in patients with very long-standing esophagitis.

Antireflux surgery (fundoplication) is indicated when GERD causes severe symptoms unresponsive to medications: (1) persistent vomiting with failure to thrive, (2) esophagitis or esophageal stricture, (3) life-threatening apneic spells, or (4) chronic pulmonary disease unresponsive to 2–3 months of medical therapy. Fundoplication also may be considered early in infants whose response to medication is likely to be poor—those with large hiatal hernia, neurologic handicap, previous tracheoesophageal (TE) fistula surgery, or severe esophagitis.

EOSINOPHILIC ESOPHAGITIS

Dysphagia, esophageal food impaction, and heartburn.

Most common in adolescent boys.

Grossly, esophagoscopy shows white eosinophilic exudates, ringlike esophageal folds, and esophageal stricture. Esophageal mucosal biopsy shows dense eosinophilic infiltrate and hyperplasia of the basal layer of the epithelium.

Clinical Findings

A. Symptoms and Signs

This recently recognized entity occurs most often in teenage boys but is reported in both sexes and all ages. A common initial presentation is an acute food impaction. The patient may have a long history of recurrent impactions and dysphagia. Heartburn is sometimes reported and suggests the diagnosis of GERD. There often is a family or personal history of atopy, asthma, and dysphagia in male relatives.

B. Laboratory Findings

The esophageal mucosa is thick and inflamed with long, shallow, linear mucosal fissures and visible circumferential mucosal rings that look a bit like the trachea (so-called trachealization). The esophagus is often sprinkled with innumerable pinpoint white exudates that superficially resemble Candida. On microscopic examination the white spots are composed of eosinophils. The basal cell layer of the esophageal mucosa is hypertrophied and infiltrated by eosinophils (usually more than 40 per 40 × light microscopic field). A lengthy stricture is often seen which tends to split during endoscopy. Serum IgE often is elevated but this is not a diagnostic finding. Specific allergens are rarely identified by skin testing even though the patient can sometimes identify foods that precipitate pain and dysphagia.

Differential Diagnosis

The most common differential conditions are peptic esophagitis and candidal esophagitis. Eosinophilic esophagitis may be part of a generalized eosinophilic gastroenteropathy, a very rare, steroid-responsive entity. Patients with eosinophilic gastroenteropathy often present with intestinal obstruction or gastric outlet obstruction caused by large local infiltrates of eosinophils in the antrum, duodenum, and cecum.

Treatment

An extremely hypoallergenic diet is effective in controlling symptoms. Such diets are useful in infants, but adherence to the diet in older children usually is poor. Beclomethasone, puffed or swallowed from a metered dose pulmonary inhaler, improves symptoms. Two puffs of beclomethasone from an inhaler twice daily using an age-appropriate metered dose is a common recommendation. Systemic corticosteroids, oral sodium cromolyn, and montelukast sodium also have been used with benefit in some patients. Esophageal dilation may be required to treat strictures. Repeat endoscopy after therapy...
often shows persistent inflammation despite good control of symptoms. The relationship between eosinophilic esophagitis and later esophageal malignancy has not been determined.

ACHALASIA OF THE ESOPHAGUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Gradual onset of distal esophageal obstruction.
- Dysphagia, esophageal food impaction, chronic pulmonary aspiration.
- Failure of lower esophageal relaxation during swallowing with abnormalities of esophageal peristalsis.
- High or low resting pressure of the lower esophageal sphincter.

Clinical Findings

A. Symptoms and Signs

Achalasia is uncommon in children younger than 5 years, but cases in those younger than 12 months have been reported. Symptoms include retrosternal pain and fullness, vomiting, and solid food impaction. Patients eat slowly and may drink large amounts of fluid with solid food. Dysphagia is relieved by repeated forceful swallowing or by vomiting. Familial cases occur in Allgrove syndrome (alacrima, adrenal insufficiency, and achalasia) and familial dysautonomia. Chronic cough, wheezing, recurrent aspiration pneumonitis, anemia, and poor weight gain are common.

B. Imaging and Manometry

Barium esophagram shows a dilated esophagus with a tapered "beak" at the GE junction. Esophageal dilation may not be present in infants because of the short duration of distal obstruction. Fluoroscopy shows disordered esophageal peristalsis. Esophageal manometry may show high resting pressure of the lower esophageal sphincter, failure of sphincter relaxation after swallowing, and abnormal esophageal peristalsis. The cause is unknown. There is a decrease in neuronal nitric oxide synthetase (nNOS) in the tissues of the lower esophageal sphincter and, possibly, local nitric oxide deficiency prevents sphincter relaxation. It is unclear whether the lack of nNOS is a secondary or primary phenomenon.

Differential Diagnosis

Congenital or peptic esophageal stricture, esophageal webs, and esophageal masses may mimic achalasia. Intestinal pseudo-obstruction, multiple endocrine neoplasia type 2b, systemic amyloidosis, and postvagotomy syndrome cause esophageal dysmotility and symptoms similar to achalasia. Teenage girls may be suspected of having an eating disorder. In Chagas disease, caused by the parasite Trypanosoma cruzi, nNOS and ganglion cells are diminished or absent in the muscular layers of the lower esophageal sphincter causing an acquired achalasia.

Treatment & Prognosis

Pneumatic dilation of the lower esophageal sphincter produces temporary relief of obstruction that may last weeks to years. Local injection of botulinum toxin paralyzes the lower esophageal sphincter and temporarily relieves obstruction. More long-lasting relief of obstruction is achieved by surgically dividing the lower esophageal sphincter (Heller myotomy). The procedure can be performed laparoscopically or thoracoscopically. Because of the shorter duration of esophageal obstruction in children, there is less secondary dilation of the esophagus. Thus, the prognosis for return or retention of some normal esophageal motor function after surgery is better than in adults.

CAUSTIC BURNS OF THE ESOPHAGUS

Ingestion of caustic solids or liquids (pH > 12) produces esophageal lesions ranging from superficial inflammation to coagulative necrosis with ulceration, perforation, mediastinitis, or peritonitis. The severity of immediate oral or laryngeal injury after ingestion does not correlate with the degree of esophageal injury. Esophageal or laryngeal obstruction from edema and exudate may occur within 24 hours. Pain may be severe. Esophageal strictures develop in areas of anatomic narrowing (thoracic inlet, GE junction, or point of compression where the left bronchus crosses the esophagus), where contact with the caustic agent is more prolonged. Strictures may develop quickly or gradually over several months. Strictures occur only with full-thickness esophageal necrosis. Shortening of the esophagus is a late complication that may cause hiatal hernia. The lips, mouth, and airway should be examined in suspected alkali ingestion. Vomiting should not be induced. Drooling is common and is not an accurate reflection of severity of esophageal burns. Oral injury is common with solid caustic agents. Intravenous corticosteroids (eg, methylprednisolone, 1–2 mg/kg/d) are given immediately to reduce oral swelling and laryngeal edema. Intravenous fluids are necessary if dysphagia prevents oral intake. Esophagoscopy, if needed, should be done within 24–48 hours after ingestion before liquefaction of tissues is complete. Treatment may be stopped if there are only first-degree burns at endoscopy. Corticosteroids may be beneficial in first- and second-degree burns.
burns but do not prevent stricture formation from circumferential third-degree burns. Repeated esophageal dilations may be necessary as a stricture develops but are not performed acutely. When radiographs show erosion into the mediastinum or peritoneum, antibiotics are mandatory. Intraluminal esophageal stenting may be beneficial during early management. Surgical replacement of the esophagus by colonic interposition or gastric tube may be needed for long strictures resistant to dilation.

Although agents such as bleach, detergents, and acids may cause esophageal irritation, it is rare for any but the strongest acids and detergents to produce full-thickness necrosis and stricture.

FOREIGN BODIES IN THE ALIMENTARY TRACT

The most common foreign bodies ingested by children are coins. Most foreign bodies pass through the GI tract without difficulty, although objects longer than 5 cm may be unable to pass the ligament of Treitz. Ingested foreign bodies tend to lodge in areas of natural constriction—valleculae, thoracic inlet, GE junction, pylorus, ligament of Treitz, and ileocecal junction. Foreign bodies lodged in the esophagus for more than 24 hours, or those causing pain or respiratory distress, should be removed. Disk-shaped batteries lodged in the esophagus should be removed immediately.

Smooth foreign bodies in the stomach, such as buttons or coins, may be monitored without attempting removal for up to several months if the child is free of symptoms. Disk-shaped batteries in the stomach will generally pass uneventfully. Straight pins, screws, and nails generally pass without incident. Large, open safety pins should be removed from the stomach because they may not pass the pyloric sphincter and may cause perforation. Wooden toothpicks should be removed. They have usually been chewed prior to accidental swallowing and carry mouth flora which may cause abscess formation if the toothpick becomes imbedded in the bowel wall. The use of balanced electrolyte lavage solutions containing polyethylene glycol may help the passage of small, smooth foreign bodies lodged in the stomach or intestine. Lavage is especially useful in hastening the passage of disk-shaped batteries or ingested tablets that may be toxic. Failure of a smooth foreign body to exit the stomach after several days suggests the possibility of gastric outlet obstruction.

Most foreign bodies can be removed from the esophagus or stomach by a skilled endoscopist. Under fluoroscopy, a Foley catheter with balloon inflated below the foreign body can be used to extract smooth, round esophageal foreign bodies if the foreign body has been present for less than a few days and if the child has not had previous esophageal surgery. Only an experienced radiologist should attempt this maneuver.
finally apathy occur. The upper abdomen may be distended after feeding, and prominent gastric peristaltic waves from left to right may be seen. An oval mass, 5–15 mm in longest dimension can be felt on deep palpation in the right upper abdomen, especially after vomiting.

B. Laboratory Findings
Hypochloremic alkalosis with potassium depletion occurs. Dehydration causes elevated hemoglobin and hematocrit. Mild unconjugated bilirubinemia occurs in 2–5% of cases.

C. Imaging
A barium upper GI series reveals retention of contrast in the stomach and a long narrow pyloric channel with a double track of barium. The hypertrophied muscle mass produces typical semilunar filling defects in the antrum. Isolated pylorospasm is common in young infants, and by itself is insufficient to make a diagnosis of pyloric stenosis. Ultrasonography shows a hypoechoic muscle ring greater than 4-mm thick with a hyperdense center.

Treatment & Prognosis
Pyloromyotomy is the treatment of choice and consists of incision down to the mucosa along the pyloric length. The procedure can be performed laparoscopically. Treatment of dehydration and electrolyte imbalance is mandatory before surgical treatment, even if it takes 24–48 hours. The outlook after surgery is excellent. Patients often vomit postoperatively as a consequence of gastritis, esophagitis, or associated GE reflux. The postoperative barium radiograph remains abnormal for many months despite relief of symptoms.

GASTRIC & DUODENAL ULCER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Localized erosions of gastric or duodenal mucosa.
- Pain and bleeding are the most common symptoms.
- Underlying severe illness, *Helicobacter pylori* infection, and nonsteroidal anti-inflammatory drugs (NSAIDs) are the most common causes.
- Diagnosis by endoscopy.

General Considerations
Gastric and duodenal ulcers occur at any age. Boys are affected more frequently than girls. In the United States, most childhood gastric and duodenal ulcers are associated with underlying illness, toxins, or drugs that cause breakdown in mucosal defenses.

Worldwide, the most common cause of gastric and duodenal ulcer is infection of the gastric mucosa with *H pylori*. Infection causes nodular gastritis and duodenal or gastric ulcer. Long-standing infection is associated with gastric lymphoid tumors and adenocarcinoma. Between 10% and 20% of North American children have antibodies against *H pylori*. Antibody prevalence increases with age, poor sanitation, crowded living conditions, and family exposure. In some developing countries, over 90% of schoolchildren have serologic evidence of past or present infection.

Illnesses predisposing to secondary ulcers include central nervous system disease, burns, sepsis, multi-organ system failure, chronic lung disease, Crohn disease, cirrhosis, and rheumatoid arthritis. The most common drugs causing secondary ulcers are aspirin, alcohol, and NSAIDs. NSAID use causes ulcers throughout the upper GI tract but most often in the stomach and duodenum.

Clinical Findings
A. Symptoms and Signs
In children younger than 6 years, vomiting and upper GI bleeding are the most common symptoms of gastric and duodenal ulcer. Older children are more likely to complain of abdominal pain. The first attack of acute *H pylori* gastritis may be accompanied by vomiting and hematemesis. Ulcers in the pyloric channel may cause gastric outlet obstruction. Chronic blood loss may cause iron-deficiency anemia. Deep penetration of the ulcer may erode into a mucosal arteriole and cause acute hemorrhage. Penetrating duodenal ulcers (especially common during cancer chemotherapy, immunosuppression and in the intensive care setting) may perforate the duodenal wall causing peritonitis or abscess.

B. Diagnostic Studies
Upper GI endoscopy is the most accurate diagnostic examination. It also allows for identification of other causes of peptic symptoms such as esophagitis, eosinophilic enteropathy, and celiac disease. Upper GI barium radiographs may show an ulcer crater. Soft signs suggestive of peptic disease in adults (duodenal spasticity and thick irregular folds) are not reliable indicators in children. Urease activity is assessed on gastric biopsies, or by evaluation of breath after administration of radiolabeled urea by mouth. *H pylori* antigens can be measured in stool and may be an effective, noninvasive test for infection. Serum antibodies against *H pylori* do not prove that there is active infection or that treatment is needed.
**CONGENITAL DUODENAL OBSTRUCTION**

**General Considerations**

Extrinsic duodenal obstruction is usually due to congenital peritoneal bands associated with intestinal malrotation, annular pancreas, or duodenal duplication. Intrinsic obstruction is caused by stenosis, mucosal diaphragm (so-called wind sock deformity), or duodenal atresia. The duodenal lumen may be obliterated by a membrane or completely interrupted with a fibrous cord between the two segments. Atresia is more often distal to the ampulla of Vater than proximal.

**Clinical Findings**

**A. Duodenal Atresia**

Maternal polyhydramnios is common and often leads to prenatal diagnosis by ultrasonography. Vomiting (usually bile-stained) and epigastric distention begin within a few hours of birth. Meconium may be passed normally. Duodenal atresia is often associated with other congenital anomalies (30%), including esophageal atresia, intestinal atresias, and cardiac and renal anomalies. Prematurity (25–50%) and Down syndrome (20–30%) are also associated. Abdominal plain radiographs show gaseous distention of the stomach and proximal duodenum (the “double-bubble” radiologic sign). With protracted vomiting, there is less air in the stomach and less abdominal distention. Absence of distal intestinal gas suggests atresia or severe extrinsic obstruction, whereas a pattern of intestinal air scattered over the lower abdomen may indicate partial duodenal obstruction. Barium enema may be helpful in determining the presence of malrotation or atresia in the lower GI tract.

**B. Duodenal Stenosis**

In this condition, duodenal obstruction is not complete. Onset of obvious obstructive symptoms may be delayed for weeks or years. Although the stenotic area is usually distal to the ampulla of Vater, the vomitus does not always contain bile. Children with Down syndrome have an increased risk of duodenal stenosis.

**Treatment & Prognosis**

Duodenoduodenostomy is performed to bypass the area of stenosis or atresia. Thoracic surgical exploration is done to ensure that no lower GI tract anomalies are present. The mortality rate is increased in infants with prematurity, Down syndrome, and associated congenital anomalies. Duodenal dilation and hypomotility from antenatal obstruction may cause duodenal dysmotility with obstructive symptoms even after surgical treatment.

**ANNULAR PANCREAS**

Annular pancreas is a rotational defect in which normal fusion of the dorsal and ventral pancreatic anlagen does...
not occur, and a ring of pancreatic tissue encircles the duodenum. The presenting symptom is duodenal obstruction. Down syndrome and congenital anomalies of the GI tract occur frequently. Polyhydramnios is common. Symptoms may develop late in childhood or even in adulthood if the obstruction is not complete in infancy. Treatment consists of duodenoduodenostomy or duodenojejunostomy without operative dissection or division of the pancreatic annulus.

**DISORDERS OF THE SMALL INTESTINE**

**INTESTINAL ATRESIA & STENOSIS**

Excluding anal anomalies, intestinal atresia or stenosis accounts for one third of all cases of neonatal intestinal obstruction (see Chapter 1). Antenatal ultrasound can identify intestinal atresia in utero; polyhydramnios occurs in most affected pregnancies. Prematurity and other congenital anomalies may be present. The localization and relative incidence of atresias and stenoses are listed in Table 20–1.

Bile-stained vomiting and abdominal distention begin in the first 48 hours of life. Multiple sites in the intestine may be affected. The overall length of the small intestine may be significantly shortened. Radiographic features include dilated loops of small bowel and absence of colonic gas. Barium enema reveals narrow-caliber microcolon because of lack of intestinal flow distal to the atresia. In over 10% of patients with intestinal atresia the mesentery is absent, and the superior mesenteric artery cannot be identified beyond the origin of the right colic and ileocolic arteries. The ileum coils around one of these two arteries, giving rise to the so-called Christmas tree deformity on contrast radiographs. The tenuous blood supply often compromises surgical anastomoses. The differential diagnosis of intestinal atresia includes Hirschsprung disease, paralytic ileus secondary to sepsis, midgut volvulus, and meconium ileus. Surgery is mandatory. Postoperative complications include short bowel syndrome and small bowel hypomotility secondary to antenatal obstruction.

**INTESTINAL MALROTATION**

**General Considerations**

The midgut extends from the duodenojejunal junction to the mid transverse colon. It is supplied by the superior mesenteric artery, which runs in the root of the mesentery. During gestation, the midgut elongates into the umbilical sac, returning to an intra-abdominal position during the 10th week of gestation. The root of the mesentery rotates in a counterclockwise direction during retraction causing the colon to cross the abdominal cavity ventrally. The cecum moves from the left to the right lower quadrant, and the duodenum crosses dorsally becoming partly retroperitoneal. When rotation is incomplete, the dorsal fixation of the mesentery is defective and shortened, so that the bowel from the ligament of Treitz to the mid transverse colon may rotate around its narrow mesenteric root and occlude the superior mesenteric artery (volvulus).

**Clinical Findings**

**A. Symptoms and Signs**

Malrotation with volvulus accounts for 10% of neonatal intestinal obstructions. Most infants present in the first 3 weeks of life with bile-stained vomiting or with overt small bowel obstruction. Intrauterine volvulus may cause intestinal obstruction or perforation at birth. The neonate may present with ascites or meconium peritonitis. Later presenting signs include intermittent intestinal obstruction, malabsorption, protein-losing enteropathy, or diarrhea. Associated congenital anomalies, especially cardiac, occur in over 25% of symptomatic patients.

**B. Imaging**

An upper GI series shows the duodenojejunal junction and the jejunum on the right side of the spine. The diagnosis of malrotation can be further confirmed by barium enema, which may demonstrate a mobile cecum located in the midline, right upper quadrant, or left abdomen.

**Treatment & Prognosis**

Surgical treatment of malrotation is the Ladd procedure. In young infants the Ladd procedure should be performed even...
if volvulus has not occurred. The duodenum is mobilized and the short mesenteric root is extended. The bowel is then fixed in a more normal distribution. Treatment of malrotation discovered in children older than age 12 months is uncertain. Because volvulus can occur at any age, surgical repair is usually recommended, even in asymptomatic children. Laparoscopic repair of malrotation is possible but is technically difficult and is never performed in the presence of volvulus.

Midgut volvulus is a surgical emergency. Bowel necrosis results from occlusion of the superior mesenteric artery. When necrosis is extensive, it is recommended that a first operation include only reduction of the volvulus with lysis of mesenteric bands. Resection of necrotic bowel should be delayed if possible until a second-look operation 24–48 hours later can be undertaken in the hope that more bowel can be salvaged. The prognosis is guarded if perforation, peritonitis, or extensive intestinal necrosis is present.

SHORT BOWEL SYNDROME

The most common cause of short bowel syndrome is neonatal intestinal resection. Necrotizing enterocolitis is the most common reason for resection (45%). Other causes include intestinal atresias (23%), gastroschisis (15%), volvulus (15%), and, less commonly, congenital short bowel, long-segment Hirschsprung disease, and bowel ischemic events. If bowel resection is extensive, the infant may be left with an intestine of insufficient length to support normal absorption and growth. Estimates of the small bowel length of a newborn range from 150–300 cm. Neonatal short bowel syndrome is defined as removal of more than 50% of the small intestinal length. In patients with 50% resection, it is almost certain that intravenous nutrition will be required for months to years to support growth.

The intestine remaining after resection does not undergo compensatory increase in length. However, if nutrition can be maintained, enterocytes will proliferate, villi will lengthen, and the intestine will elongate in proportion to the child’s increasing height. These adaptations may eventually be sufficient for the patient’s nutritional needs. Achieving independence from intravenous nutrition is less likely when less than 30 cm of small intestine remain after surgery. An intact colon and intact ileocecal sphincter are factors improving prognosis in short bowel syndrome. Liver failure (a consequence of intravenous nutrition, recurrent infection, and other injuries) is the most common cause of death in patients with short bowel syndrome. Mortality among all infants with short bowel syndrome is about 10–15%. Intestinal transplantation is an option for children with very short residual intestinal segments.

INTUSSUSCEPTION

Intussusception is the most frequent cause of intestinal obstruction in the first 2 years of life. It is three times more common in males than in females. In 85% of cases the cause is not apparent. Small bowel polyp, Meckel diverticulum, omphalomesenteric remnant, duplication, Henoch-Schönlein purpura, lymphoma, lipoma, parasites, foreign bodies, and viral enteritis with hypertrophy of Peyer patches all have been implicated as causes. Intussusception of the small intestine occurs in patients with celiac disease and cystic fibrosis related to the bulk of stool in the terminal ileum. In children older than 6 years, lymphoma is the most common cause. Intermittent small bowel intussusception is a rare cause of recurrent abdominal pain.

In its usual form, the intussusception starts just proximal to the ileocecal valve and extends for varying distances into the colon. The terminal ileum telescopes into the colon. Swelling, hemorrhage, incarceration, arterial and venous compromise, and necrosis of the intussuscepted ileum may occur, as well as intestinal perforation and peritonitis.

Clinical Findings

Characteristically, a thriving infant 3–12 months of age develops recurring paroxysms of abdominal pain with screaming and drawing up of the knees. Vomiting and diarrhea occur soon afterward (90% of cases), and bloody bowel movements with mucus appear within the next 12 hours (50%). The child is characteristically lethargic between paroxysms and may be febrile. The abdomen is tender and often distended. A sausage-shaped mass may be palpated, usually in the upper mid abdomen. An intussusception can persist for several days if obstruction is not complete, and patients may present with intermittent attacks of enterocolitis. In older children, sudden attacks of abdominal pain may be related to chronic recurrent intussusception with spontaneous reduction.

Treatment

Barium enema and air enema are both diagnostic and therapeutic. Reduction of the intussusception by barium enema should not be attempted if signs of strangulated bowel, perforation, or toxicity are present. Air insufflation of the colon under fluoroscopic guidance is a safe alternative to barium enema that has excellent diagnostic sensitivity and specificity without the risk of contaminating the abdominal cavity with barium. Care is required in performing either air or barium enema because ischemic damage to the colon secondary to vascular compromise increases the risk of perforation.

Surgery is required in extremely ill patients, in patients with evidence of bowel perforation, or in those in whom hydrostatic or pneumatic reduction has been unsuccessful (25%). Surgery has the advantage of identifying a lead point such as a Meckel diverticulum. Surgical reduction of intus-
suspension is associated with a lower recurrence rate than pneumatic reduction.

**Prognosis**

The prognosis relates directly to the duration of the intussusception before reduction. The mortality rate with treatment is 1–2%. The patient should be observed carefully after hydrostatic or pneumatic reduction because intussusception recurs within 24 hours in 3–4% of patients.

**INGUINAL HERNIA**

A peritoneal sac precedes the testicle as it descends from the genital ridge to the scrotum. The lower portion of this sac envelops the testis as the tunica vaginalis, and the remainder normally atrophies by the time of birth forming a cord (processus vaginalis). In some cases, peritoneal fluid may become trapped in the tunica vaginalis (noncommunicating hydrocele). If the processus vaginalis remains open, peritoneal fluid or an abdominal structure may be forced into it (indirect inguinal hernia).

Inguinal hernias are most often indirect and occur more frequently (9:1) in boys than in girls. Hernias may be present at birth or may appear at any age. The incidence in preterm male infants is close to 5%. Inguinal hernia is reported in 30% of male infants weighing 1000 g or less.

**Clinical Findings**

No symptoms are associated with an empty processus vaginalis. In most cases, a hernia is a painless inguinal swelling. The mother of the infant may be the only person to see the mass, as it may retract when the infant is active, cold, frightened, or agitated during the physical examination. There may be a history of inguinal fullness associated with coughing or long periods of standing, or there may be a firm, globular, and tender swelling, sometimes associated with vomiting and abdominal distention. In some instances, a herniated loop of intestine may become partially obstructed, leading to pain and partial intestinal obstruction. Rarely, bowel becomes trapped in the hernia sac, and complete intestinal obstruction occurs. Gangrene of the hernia contents or testis may occur. In girls, the ovary may prolapse into the hernia sac presenting as a mass below the inguinal ligament. A suggestive history is often the only criterion for diagnosis, along with the “silk glove” feel of the rubbing together of the two walls of the empty hernia sac.

**Differential Diagnosis**

Inguinal lymph nodes may be mistaken for a hernia. Nodes are usually multiple with more discrete borders. A hydrocele of the cord should transilluminate. An undescended testis is usually mobile in the canal and is associated with absence of the gonad in the scrotum.

**Treatment**

Incarceration of an inguinal hernia is more likely to occur in boys and in children younger than 10 months of age. Manual reduction of incarcerated inguinal hernias can be attempted after the sedated infant is placed in the Trendelenburg position with an ice bag on the affected side. Manual reduction is contraindicated if incarceration has been present for more than 12 hours or if bloody stools are noted. Surgery is usually indicated if a hernia has ever incarcerated. Hydroceles frequently resolve by age 2 years. Controversy remains about whether the side opposite a unilateral hernia should be surgically explored. Exploration of the unaffected groin can document an open processus vaginalis, but patency does not always guarantee that herniation will occur, especially in patients older than age 1 year, in whom the risk of contralateral hernia is about 10%.

**UMBILICAL HERNIA**

Umbilical hernias are more common in preterm than in full-term infants and more common in black than in white infants. Small bowel may incarcerate in small-diameter umbilical hernias. Most umbilical hernias regress spontaneously if the fascial defect has a diameter of less than 1 cm. Large defects and hernias persisting after age 4 years should be treated surgically. Reducing the hernia and strapping the skin over the abdominal wall defect does not accelerate the healing process.

**PATENT OMPHALOMESENTERIC DUCT**

The omphalomesenteric duct is an embryonic remnant connecting the ileum to the undersurface of the umbilicus. It may be patent, completely occluded as a fibrous cord, or may have blind cystic areas. Fecal discharge from the umbilicus suggests a patent omphalomesenteric duct. A fibrous cord may become the focal point of an intestinal volvulus. Mucoid umbilical discharge may indicate a mucocoele in the omphalomesenteric remnant with an opening at the umbilicus. A closed mucocoele may protrude through the umbilicus and be mistaken for an umbilical granuloma because it is firm and bright red. Cauterization of a mucocoele is not recommended. Surgical excision of omphalomesenteric remnants is indicated. Ultrasound examination or abdominal computed tomography (CT) can help confirm the diagnosis of omphalomesenteric duct remnant.

**MECKEL DIVERTICULUM**

Meckel diverticulum is the most common form of omphalomesenteric duct remnant. It is usually located on the antimesenteric border of the mid to distal ileum. It occurs in 1.5% of the population and in the majority of cases causes no
symptoms. Diverticula may be lined by ileal, gastric, pancreatic, jejunal, or colonic mucosa. Familial cases have been reported. If complications occur, they are three times more common in males than in females. More than 50% of complications occur in the first 2 years of life.

**Clinical Findings**

**A. Symptoms and Signs**

Forty to 60% of symptomatic patients have painless episodes of maroon or melanotic rectal bleeding. The bleeding is due to deep ileal ulcers adjacent to the diverticulum caused by acid secreted by heterotopic gastric tissue. Occult bleeding is less common. Intestinal obstruction occurs in 25% of symptomatic patients as a result of ileocolonic intussusception. Intestinal volvulus may occur around a fibrous remnant of the vitelline duct extending from the tip of the diverticulum to the abdominal wall. In some patients, entrapment of bowel under a band running between the diverticulum and the base of the mesentery occurs. Meckel diverticula may be trapped in an inguinal hernia (Littre hernia). Diverticulitis occurs in 10–20% of symptomatic patients and is clinically indistinguishable from acute appendicitis. Perforation and peritonitis may occur. Chronic recurrent abdominal pain is rarely the only symptom.

**B. Imaging**

Diagnosis of Meckel diverticulum is seldom made on barium radiograph. Technetium-99 (99mTc)-pertechnetate is taken up by the heterotopic gastric mucosa in the diverticulum and outlines the diverticulum on a nuclear scan. Giving pentagastrin or cimetidine before administering the radionuclide increases 99mTc-pertechnetate uptake and retention by the heterotopic gastric mucosa and can increase the sensitivity of the test. Angiography or tagged red cell scan may be useful when bleeding is brisk.

**Treatment & Prognosis**

Treatment is surgical. At laparoscopy or laparotomy, the ileum proximal and distal to the diverticulum may reveal ulcerations and heterotopic gastric tissue adjacent to the neck of the diverticulum. The prognosis for Meckel diverticulum is good.

**ACUTE APPENDICITIS**

**General Considerations**

Acute appendicitis is the most common indication for emergency abdominal surgery in childhood. The frequency increases with age and peaks between 15 and 30 years. Obstruction of the appendix by fecalith (25%) is a common predisposing factor. Parasites may rarely cause obstruction (especially ascarids) and most of the remaining cases are idiopathic.

The incidence of perforation is high in childhood (40%), especially in children younger than age 2 years, in whom pain is often poorly localized and symptoms nonspecific. To avoid delay in diagnosis, it is important to maintain close communication with parents and perform a thorough initial physical examination with sequential examinations at frequent intervals over several hours to correctly interpret the evolving symptoms and signs.

**Clinical Findings**

**A. Symptoms and Signs**

The typical patient has fever and periumbilical abdominal pain, which then localizes to the right lower quadrant with signs of peritoneal irritation. Anorexia, vomiting, constipation, and diarrhea also occur. Contrary to the vomiting of acute gastroenteritis which usually precedes abdominal pain, vomiting in appendicitis usually follows the onset of pain and is often bilious. The clinical picture is frequently atypical, especially in young children and infants. A rectal examination may clarify the site of tenderness or reveal a localized appendiceal mass. Serial examinations are critical in differentiating appendicitis from the many other conditions that transiently mimic its symptoms.

**B. Laboratory Findings**

The white blood cell count is seldom higher than 15,000/μL. Pyuria, fecal leukocytes, and guaiac-positive stool are sometimes present.

**C. Imaging**

A radio-opaque fecalith reportedly is present in two thirds of cases of ruptured appendix. In experienced hands, ultrasonography of the appendix shows a noncompressible, thickened appendix in 93% of cases. A localized fluid collection adjacent to or surrounding the appendix may also be seen. Abdominal CT after rectal instillation of contrast with thin cuts in the area of the appendix may be diagnostic. Indium-labeled white blood cell scan may localize to an inflamed appendix. Enlarged mesenteric lymph nodes are a nondiagnostic finding.

**Differential Diagnosis**

The presence of pneumonia, pleural effusion, urinary tract infection, right-sided kidney stone, cholecystitis, perihepatitis, and pelvic inflammatory disease may mimic appendicitis. Other medical and surgical conditions causing acute abdomen should also be considered (see Table 20–8).

**Treatment & Prognosis**

Exploratory laparotomy or laparoscopy is indicated when the diagnosis of appendicitis cannot be ruled out after a period of close observation. Postoperative antibiotic therapy
is reserved for patients with gangrenous or perforated appendix. A single intraoperative dose of cefoxitin or ceftetan is recommended for all patients to prevent postoperative infection. The mortality rate is less than 1% during childhood, despite the high incidence of perforation. In uncomplicated nonruptured appendicitis, a laparoscopic approach is associated with a shortened hospital stay.

DUPLICATIONS OF THE GASTROINTESTINAL TRACT

Duplications are congenital spherical or tubular structures found most commonly in the ileum. The other common locations of duplication are the duodenum, rectum, and esophagus. Duplications usually contain fluid and sometimes blood if necrosis has taken place. Most duplications are attached to the mesenteric side of the gut. They generally do not communicate with the intestinal lumen but share a common muscular coat. The epithelial lining of the duplication is usually of the same type as the bowel from which it originates. Some duplications (neuroenteric cysts) are attached to the spinal cord and are associated with hemivertebrae and anterior or posterior spina bifida.

Symptoms of vomiting, abdominal distention, colicky pain, rectal bleeding, partial or total intestinal obstruction, or an abdominal mass may start in infancy. Diarrhea and malabsorption may result from bacterial overgrowth in communicating duplications. Physical examination may reveal a rounded, smooth, movable mass, and barium radiograph or CT of the abdomen may show a noncalcified cystic mass displacing other organs. 99mTc-pertechnetate scan may help identify duplications containing gastric mucosa. Duplications of the ileum can give rise to an intussusception. Prompt surgical treatment is indicated.

DISORDERS OF THE COLON

CONGENITAL AGANGLIONIC MEGACOLON (HIRSCHSPRUNG DISEASE)

General Considerations

Hirschsprung disease results from an absence of ganglion cells in the mucosal and muscular layers of the colon. Neural crest cells fail to migrate into the mesodermal layers of the gut during gestation, possibly secondary to abnormal end-organ cell surface receptors or local deficiency of nitric oxide synthesis. The absence of ganglion cells results in failure of the colonic muscles to relax in front of an advancing bolus. The rectum (30%) or rectosigmoid (44%) is usually affected. The entire colon may be aganglionic (8%). Segmental aganglionosis is rare and is probably an acquired ischemic lesion.

The aganglionic segment has normal or slightly narrowed caliber with dilation of the normal colon proximal to the obstructing aganglionic segment. The mucosa of the dilated colonic segment may become thin and inflamed, causing diarrhea, bleeding, and protein loss (enterocolitis).

A familial pattern has been described, particularly in total colonic aganglionosis. The disease is four times more common in boys than girls, and 10–15% of patients have Down syndrome. Mutations in the ret proto-oncogene have been identified in about 15% of cases.

Clinical Findings

A. Symptoms and Signs

Failure of the newborn to pass meconium, followed by vomiting, abdominal distention, and reluctance to feed, suggest the diagnosis of Hirschsprung disease. Enterocolitis manifested by fever, explosive diarrhea, and prostration, is reported in approximately 50% of affected newborns. Enterocolitis may lead to inflammatory and ischemic changes in the colon, with perforation and sepsis. In some patients, especially those with short segments involved, symptoms are not obvious at birth. In later infancy, alternating obstipation and diarrhea predominate. The older child is more likely to have constipation alone. The stools are foul-smelling and ribbon-like. The abdomen is distended with prominent veins. Peristaltic waves are visible and fecal masses palpable. Intermittent bouts of intestinal obstruction, hypochromic anemia, hypoproteinemia, and failure to thrive are common. Encopresis is rare.

On digital rectal examination, the anal canal and rectum are devoid of fecal material despite obvious retained stool on abdominal examination or radiographs. If the aganglionic segment is short, there may be a gush of flatus and stool as the finger is withdrawn.

Infants of diabetic mothers may have similar symptoms and, in this setting, small left colon syndrome should be suspected. Meglumine diatrizoate (Gastrografin) enema is both diagnostic and therapeutic in small left colon syndrome as it reveals a meconium plug in the left colon, which is often passed during the diagnostic radiograph. The left colon is narrow but usually functional. In a small proportion of patients with small left colon, Hirschsprung disease may later be found.

B. Laboratory Findings

Ganglion cells are absent in both the submucosal and muscular layers of involved bowel. Special stains may show nerve trunk hypertrophy and increased acetylcholinesterase activity. Ganglionated bowel above the aganglionic segment is sometimes found to contain more than normal numbers of ganglion cells in abnormal locations (neuronal dysplasia). This finding is sometimes associated with persistent motor dysfunction of the remnant colon.
C. Imaging

Plain abdominal radiographs may reveal dilated proximal colon and absence of gas in the pelvic colon. Barium enema using a catheter without a balloon and with the tip inserted barely beyond the anal sphincter usually demonstrates a narrow distal segment with a sharp transition to the proximal dilated (normal) colon. The transition zone may not be seen in neonates since the normal proximal bowel has not had time to become dilated. Retention of barium for 24–48 hours is not diagnostic of Hirschsprung disease in older children as it typically occurs in retentive constipation as well. Barium retention is a more reliable sign in neonates.

D. Special Examinations

Rectal manometric testing reveals failure of reflex relaxation of the internal anal sphincter after distention of the rectum in all patients with Hirschsprung disease, regardless of the length of the aganglionic segment. In occasional patients, a nonrelaxing internal anal sphincter is the only abnormality. This condition is often called “ultrashort segment Hirschsprung disease.”

Differential Diagnosis

Hirschsprung disease accounts for 15–20% of cases of neonatal intestinal obstruction. It must be differentiated from the small left colon syndrome by biopsy. In childhood, Hirschsprung disease must be differentiated from retentive constipation. In older infants and children it can also be confused with celiac disease because of the striking abdominal distention and failure to thrive.

Treatment & Prognosis

Treatment is surgical. Diverting colostomy (or ileostomy) is performed proximal to the aganglionic segment. In unstable infants, resection of the aganglionic segment may be postponed. At the time of definitive surgery, the transition zone between ganglionated and nonganglionated bowel is identified. Aganglionic bowel is resected, and a pull-through of ganglionated bowel to the preanal rectal remnant is made. Several surgical techniques, including laparoscopic pull-through, are in use. In children with ultrashort segment disease, an internal anal sphincter myotomy or botulinum toxin injection of the internal anal sphincter may control symptoms.

Complications after surgery include fecal retention, fecal incontinence, anastomotic breakdown, or anastomotic stricture. Postoperative obstruction may result from inadvertent retention of a distal aganglionic colon segment or postoperative destruction of ganglion cells secondary to vascular impairment. Neuronal dysplasia of the remaining bowel may produce a pseudo-obstruction syndrome. Enterocolitis occurs postoperatively in 15% of patients.

CONSTITUTION

Chronic constipation in childhood is defined as two or more of the following characteristics for 2 months: (1) less than 3 bowel movements per week; (2) more than 1 episode of encopresis per week; (3) impaction of the rectum with stool; (4) passage of stool so large it obstructs the toilet; (5) retentive posturing and fecal withholding; and (6) pain with defecation. Retention of feces in the rectum results in encopresis (involuntary fecal leakage) in 60% of children with constipation. Most constipation in childhood is a result of voluntary or involuntary retentive behavior (chronic retentive constipation). About 2% of healthy primary school children have chronic retentive constipation. The ratio of males to females may be as high as 4:1. Constipation due to organic causes is much rarer.

Clinical Findings

Infants younger than age 3 months often grunt, strain, and turn red in the face while passing normal stools. This pattern may be viewed erroneously as constipation. Failure to appreciate this normal developmental pattern may lead to the unwise use of laxatives or enemas. Infants and children may, however, develop the ability to ignore the sensation of rectal fullness and retain stool. Many factors reinforce this behavior, which results in impaction of the rectum and overflow incontinence or encopresis. Among these are painful defecation; skeletal muscle weakness; psychological issues, especially those relating to control and authority; modesty and distaste for school bathrooms; medications; and other factors listed in Table 20–2. The dilated rectum gradually becomes less sensitive to fullness, thus perpetuating the problem.

Differential Diagnosis

It is important to distinguish chronic retentive constipation from Hirschsprung disease. Features distinguishing these two entities are summarized in Table 20–3.

Treatment

Increased intake of high-residue foods such as bran, whole wheat, fruits, and vegetables may be sufficient therapy in mild constipation. Although extremes of dehydration may result in constipation, the most likely response to increased fluid intake in normal children is increased urination with little effect on defecation.

If diet change alone is ineffective, medications may be required. Barley malt extract (Maltsupex), 1–2 tsp added to feedings two or three times daily, or polyethylene glycol solution (MiraLax), 0.8–1 g/kg/d, are safe stool softeners in infants and children. Stool softeners such as dioctyl sodium sulfosuccinate, 5–10 mg/kg/d, may be less effective in children with voluntary stool retention. Stimulant laxatives such as standardized extract of senna fruit (Senokot syrup, Ex-Lax) can be used for short periods to relieve fecal impaction.
If encopresis is present, treatment should start with relieving fecal impaction. Disimpaction can be achieved in several ways, including medications such as hypertonic phosphate or saline enemas, mineral oil (2–3 mL/kg/d), and nonabsorbable osmotic agents such as polyethylene glycol (MiraLax, 1 g/kg/d) and milk of magnesia (1–2 mL/kg/d). Effective stool softeners should thereafter be given regularly in doses sufficient to induce two or three loose bowel movements per day. After several weeks to months of regular loose stools, stool softeners can be tapered and stopped. Mineral oil should not be given to nonambulatory infants, physically handicapped or bed-bound children, or any child with GE reflux. Aspiration of mineral oil may cause lipid pneumonia. A multiple vitamin supplement is recommended while mineral oil is given. Recurrence of encopresis is common and should be treated promptly with a short course of stimulant laxatives or an enema. Psychiatric consultation may be indicated for patients with resistant symptoms or severe emotional disturbances.

**ANAL FISSURE**

Anal fissure is a slitlike tear in the squamous epithelium of the anus, usually secondary to the passage of large, hard fecal...
masses. Anal stenosis, anal crypt abscess, and trauma can be contributory factors. Sexual abuse must be considered in children with large, irregular, or multiple anal fissures. Anal fissures may be the presenting sign of Crohn disease in older children.

The infant or child with anal fissure typically cries with defecation and will try to hold back stools. Sparse, bright red bleeding is seen on the outside of the stool or on the toilet tissue following defecation. The fissure can often be seen if the patient is examined in a knee-chest position with the buttocks spread apart. When a fissure cannot be identified, it is essential to rule out other causes of rectal bleeding such as juvenile polyp, perianal inflammation due to group A β-hemolytic streptococcus, or inflammatory bowel disease. Anal fissures should be treated promptly to break the constipation → fissure → pain → retention → constipation cycle. A stool softener should be given. Anal dilation relieves sphincter spasm. Warm sitz baths after defecation may be helpful. Rarely, silver nitrate cauterization or surgery is indicated. Anal surgery should be avoided in patients with Crohn disease because of the high risk of recurrence and progression after surgery.

CONGENITAL ANORECTAL ANOMALIES

1. Anterior Displacement of the Anus

Anterior displacement of the anus is a common anomaly of infant girls. Its usual presentation in infants is constipation and straining with stool. On physical examination, the anus looks normal but is ventrally displaced, located close to the vaginal fourchette (in females) or to the base of the scrotum (in males). The diagnosis is made in girls if the distance from the vaginal fourchette to the center of the anal opening is less than 25% of the total distance from fourchette to coccyx. In boys the diagnosis is made if the distance from the base of the scrotum to the anal aperture is less than 33% of the total distance from scrotum to coccyx. In severe anterior displacement, when the anal opening is located less than 10% of the distance from the vaginal fourchette to the coccyx, the anal sphincter muscle may not completely encircle the anal opening and severe obstipation similar to that seen in imperforate anus may occur. Indeed, extreme anterior displacement of the anus may be a form of imperforate anus. Surgery is not needed in most cases. Stool softeners or occasional glycerin suppositories usually relieve straining. This problem improves significantly by age 3–4 years as normal toddler lordosis disappears. A thorough investigation for imperforate anus should be performed in children with severe persistent symptoms, and an anal cutback operation may be needed.

2. Anal Stenosis

Anal stenosis usually presents in the newborn period. The anal aperture may be very small and filled with a dot of meconium. Defecation is difficult, with ribbon-like stools, blood and mucus per rectum, fecal impaction, and abdominal distention. This malformation accounts for about 10% of anorectal anomalies. Anal stenosis may not be apparent at birth because the anus looks normal. Rectal bleeding in a straining infant often leads to a rectal examination which reveals a tight ring in the anal canal. Dilation of the anal ring is usually curative but may have to be repeated daily for several weeks.

3. Imperforate Anus

Imperforate anus in its numerous forms accounts for 75% of all anorectal anomalies. These anomalies are often complicated by associated anomalies of the urinary and genital tract. They are more common in males than in females and require careful diagnostic evaluation immediately to assess the extent of bowel, urinary, genital, and other organ system anomalies, including spinal cord and heart.

Infants with low imperforate anus fail to pass meconium. There may be a greenish bulging membrane obstructing the anal aperture. Perforation of the anal membrane is a relatively simple surgical procedure. A skin tag shaped like a “bucket handle” is seen on the perineum of some males below which a stenotic aperture can be seen. The aperture is sometimes surrounded by normal anal musculature, but in many cases the aperture is a rectoperineal fistula and the anal musculature is displaced posteriorly or is absent. Eighty to 90% of patients with low imperforate anus are continent after surgery.

In high imperforate anus, physical examination usually shows no anal musculature. There may be a rectoperineal, rectovesicular, rectourethral, or rectovaginal fistula; hypoplastic buttocks; cloacal anomalies; and sometimes, evidence of distal neurologic deficit. It is critical in these cases to fully evaluate the complex anatomy and neurologic function before attempting corrective surgery. A diverting colostomy is usually performed to protect the urinary tract and relieve obstruction. After reparative surgery, only 30% of patients with high imperforate anus achieve fecal continence.

PSEUDOMEMBRANOUS ENTEROCOLITIS

Pseudomembranous enterocolitis occurs when previous antibiotic use allows overgrowth of Clostridium difficile in the colon and toxin production. The onset of colitis occurs from 1–14 days after initiation of antibiotic therapy and can occur up to 30 days after antibiotics have been discontinued. Clindamycin was one of the first antibiotics associated with pseudomembranous colitis. Almost all antibiotics are now recognized to be potential causes, although erythromycin seems less likely than most. In pediatric patients, amoxicillin and cephalosporins are commonly associated with pseudomembranous enterocolitis, probably because of their widespread use. Although antibiotic
use is the most common antecedent of pseudomembranous colitis, previous GI surgery and antimetabolite therapy in cancer patients are also associated with its development.

*C. difficile* secretes enterotoxins that cause necrotizing inflammation of the colon mucosa. The patient characteristically has fever, abdominal distention, tenesmus, diarrhea, and generalized abdominal tenderness. Chronic presentations with low-grade fever, diarrhea, and abdominal pain have been described. Diarrheal stools contain sheets of neutrophils and sometimes gross blood. Plain abdominal radiographs show a thickened colon wall and ileus. On colonoscopy, the colon is covered by small, raised white plaques (pseudomembranes) with areas of apparently normal bowel in between. Biopsy specimens show “exploding crypts”—an eruption of white cells that appears to be shooting out of affected crypts. Stool cultures often show overgrowth of *Staphylococcus aureus*, which is probably an opportunistic organism growing in the necrotic tissue. *C. difficile* can be cultured in specialized laboratories. Identification of stool toxins is the usual method of diagnosis. Infants up to 18–24 months of age may have toxins in the stool but do not develop disease or require therapy. Infants do not have sufficient receptors for the toxins to produce disease.

The treatment of pseudomembranous colitis consists of stopping antibiotics and instituting therapy with oral vancomycin (30–50 mg/kg/d) or metronidazole (30 mg/kg/d). Vancomycin is many times more expensive than metronidazole and no more efficacious. Metronidazole can be given orally in patients with vomiting or ileus. Relapse occurs after treatment in 10–50% of patients because of exsporulation of residual spores in the colon. Retreatment with the same antibiotic regimen is usually effective, but multiple relapses are possible and may be a significant management problem. Ulcerative colitis may be an underlying problem in cases of apparent recurrent *C. difficile*.

### DISORDERS OF THE PERITONEAL CAVITY

**PERITONITIS**

**Primary bacterial peritonitis** accounts for less than 2% of childhood peritonitis. The most common causative organisms are *Escherichia coli*, other enteric organisms, hemolytic streptococci, and pneumococci. Primary peritonitis occurs in patients with splenectomy, splenic dysfunction, or ascites (nephrotic syndrome, advanced liver disease, kwashiorkor). It also occurs in infants with pyelonephritis or pneumonia.

**Secondary peritonitis** is much more common. It is associated with peritoneal dialysis, penetrating abdominal trauma, or ruptured viscus. The organisms associated with secondary peritonitis vary with the cause. Organisms not commonly pathogenic such as *Staphylococcus epidermidis* and *Candida* may cause secondary peritonitis in patients receiving peritoneal dialysis. Multiple enteric organisms may be isolated after penetrating abdominal injury, bowel perforation, or ruptured appendicitis. Intra-abdominal abscesses may form in pelvic, subhepatic, or subphrenic areas, but discrete localization of infection is less common in young infants than in adults.

Symptoms of peritonitis include abdominal pain, fever, nausea, vomiting, acidosis, and shock. Respirations are shallow. The abdomen is tender, rigid, and distended, with involuntary guarding. Bowel sounds may be absent. Diarrhea is fairly common in primary peritonitis and less so in secondary peritonitis. Most peritonitis is an acute medical emergency. In patients receiving peritoneal dialysis, peritonitis can be a chronic infection causing milder symptoms.

Leukocyte count is high initially (> 20,000/μL) with a predominance of immature forms, and later may fall to neutropenic levels, especially in primary peritonitis. Plain abdominal radiographs and CT scan will confirm the presence of ascites. Bacterial peritonitis should be suspected if paracentesis fluid contains more than 500 leukocytes/μL or more than 32 mg/dL of lactate; if it has a pH less than 7.34; or if the pH is over 0.1 pH unit less than arterial blood pH. Diagnosis is made by Gram stain and culture, preferably of 5–10 mL of fluid for optimal yield. The blood culture is often positive in primary peritonitis.

Antibiotic treatment and supportive therapy for dehydration, shock, and acidosis are indicated. Surgical treatment of the underlying cause of secondary peritonitis is critical. Removal of infected peritoneal dialysis catheters in patients with secondary peritonitis is sometimes necessary and almost always required if *Candida* infection is present.

### CHYLOUS ASCITES

Neonatal chylous ascites may be due to congenital infection or developmental abnormality of the lymphatic system (intestinal lymphangiectasia). If the thoracic duct is involved, chylothorax may be present. Later in life, chylous ascites may result from congenital lymphangiectasia, retroperitoneal or lymphatic tumors, peritoneal bands, abdominal trauma, or infection, or it may occur after cardiac or abdominal surgery. It may be associated with intestinal malrotation.

#### Clinical Findings

**A. Symptoms and Signs**

Both congenital and acquired lymphatic obstruction cause chylous ascites, diarrhea, and failure to thrive. The abdomen is distended, with a fluid wave and shifting dullness. Unilateral or generalized peripheral edema may be present.

**B. Laboratory Findings**

Laboratory findings include hypoalbuminemia, hypogammaglobulinemia, and lymphopenia. Ascitic fluid contains...
lymphocytes and has the biochemical composition of chyle if
the patient has just been fed; otherwise, it is indistinguishable
from ascites secondary to cirrhosis.

**Differential Diagnosis**
Chylous ascites must be differentiated from ascites due to
liver disease and in the older child, from constrictive peri-
carditis, chronic elevated right heart pressure, malignancy,
infection, or inflammatory diseases causing lymphatic
obstruction. In the newborn, urinary ascites from anatomic
abnormalities of the kidney or collecting system must be
considered. A simple test to diagnose urinary ascites is urea
nitrogen or creatinine concentration of abdominal fluid.
Neither of these is present in chylous or hepatic ascites

**Complications & Sequelae**
Chylous ascites caused by intestinal lymphatic obstruction is
associated with fat malabsorption and protein loss. Intestinal
loss of albumin and γ-globulin may lead to edema and
increase the risk of infection. Rapidly accumulating chylous
ascites may cause respiratory complications. The primary
infections and malignancies causing chylous ascites may be
life-threatening.

**Treatment & Prognosis**
Little can be done to correct congenital abnormalities due to
hypoplasia, aplasia, or ectasia of the lymphatics unless they
are surgically resectable. Treatment is supportive, consisting
mainly of a very high-protein diet and careful attention to
infections. Shunting of peritoneal fluid into the venous
system is sometimes effective. A fat-free diet supplemented
with medium-chain triglycerides decreases the formation of
chylous ascites. Total parenteral nutrition may rarely be
necessary. Infusions of albumin generally provide only tem-
porary relief and are rarely used for chronic management. In
the neonate, congenital chylous ascites may spontaneously
disappear following one or more paracenteses and a
medium-chain triglyceride diet.

Chye JK et al: Neonatal chylous ascites: Report of 3 cases and
9099650].

**GASTROINTESTINAL
TUMORS & MALIGNANCIES**

**JUVENILE POLYPS**
Juvenile polyps are usually pedunculated and solitary. The
head of the polyp is composed of hyperplastic glandular and
vascular elements, often with cystic transformation. Juvenile
polyps are benign, and 80% occur in the rectosigmoid. Their
incidence is highest between ages 3 and 5 years, and they are
rare before age 1 year and usually autoamputate by age 15
years. They are more frequent in boys. The painless passage
of small amounts of bright red blood on a normal or
constipated stool is the most frequent manifestation. Abdominal pain is rare, but a juvenile polyp can be the lead
point for an intussusception. Low-lying polyps may prolapse
during defecation.

Rarely, many juvenile polyps may be present in the colon,
causing anemia, diarrhea, and protein loss. A few cases of
generalized juvenile polyposis involving the stomach, small
bowel, and colon have been reported. These cases are associ-
ated with a slightly increased risk of cancer.

Colonoscopy is diagnostic and therapeutic when polyps
are suspected. After removal of the polyp by electrocautery,
nothing further should be done if histologic findings con-
firm the diagnosis. There is a slight risk of developing further
juvenile polyps. Other polyposis syndromes are summarized
in Table 20–4.

**CANCERS OF THE ESOPHAGUS,
SMALL BOWEL, & COLON**

**Esophageal cancer** is rare in childhood. Cysts, leiomyomas,
and hamartomas predominate. Caustic injury of the esopha-
gus increases the very long-term risk of squamous cell
carcinoma. Chronic peptic esophagitis is associated with
Barrett esophagus, a precancerous lesion. Simple GE reflux
in infancy without esophagitis is not a risk for cancer of the
esophagus.

The most common **gastric or small bowel cancer** in
children is lymphoma or lymphosarcoma. Intermittent
abdominal pain, abdominal mass, intussusception, or a
ceeliac-like picture may be present. Carcinoid tumors are
usually benign and most often an incidental finding in the
appendix. Metastasis is rare. The carcinoid syndrome (flush-
ing, sweating, hypertension, diarrhea, and vomiting), associ-
ated with serotonin secretion, only occurs with metastatic
carcinoid tumors.

**Adenocarcinoma of the colon** is rare in childhood. The
transverse colon and rectosigmoid are the two most com-
monly affected sites. The low 5-year survival rate relates to
the nonspecificity of presenting complaints and the large
percentage of undifferentiated types. Children with a family
history of colon cancer, chronic ulcerative colitis, or familial
polyposis syndromes are at greater risk.

**MESENTERIC CYSTS**

These rare tumors may be small or large, single or multiloc-
ulated. They are thin-walled and contain serous, chylous, or
hemorrhagic fluid. They are commonly located in the small
bowel mesentery but are also found in the mesocolon. Most
mesenteric cysts cause no symptoms. Traction on the mesen-
tery may lead to colicky abdominal pain, which can be mild
and recurrent but may appear acutely with vomiting. Volvu-
In the gastrointestinal tract, a mass may occur around a cyst, and hemorrhage into a cyst may be mild or hemodynamically significant. A rounded mass can occasionally be palpated or seen on radiograph displacing adjacent intestine. Abdominal ultrasonography is usually diagnostic. Surgical removal is indicated.

### Intestinal Hemangioma

Hemangiomas of the bowel may cause acute or chronic blood loss. They may also cause intussusception, local stricture, or intramural hematoma. Thrombocytopenia and consumptive coagulopathy are occasional complications. Some lesions are telangiectasias (Rendu-Osler-Weber syndrome), and others are capillary hemangiomas. The largest group is cavernous hemangiomas, which are composed of large, thin-walled vessels arising from the submucosal vascular plexus. They may protrude into the lumen as polypoid lesions or may invade the intestine from mucosa to serosa.

### Acute Diarrhea

Viruses are the most common cause of acute gastroenteritis in developing and developed countries. Bacterial and parasitic enteric infections are discussed in Chapters 40 and 41. Of the viral agents causing enteric infection, rotavirus, a 67-nm double-stranded RNA virus with at least eight serotypes, is the most common. As with most viral pathogens, rotavirus affects the small intestine, caus-

*Autosomal dominant.

*Autosomal recessive.
ing voluminous watery diarrhea without leukocytes or blood. In the United States, rotavirus mainly affects infants between 3 and 15 months. Peak incidence in the United States is in the winter with sporadic cases occurring at other times. The virus is transmitted via the fecal-oral route and survives for hours on hands and for days on environmental surfaces.

1. Rotavirus Infection

The incubation period for rotavirus is 24–48 hours. Vomiting is the first symptom in 80–90% of patients, followed within 24 hours by low-grade fever and watery diarrhea. Diarrhea usually lasts 4–8 days but may last longer in young infants or immunocompromised patients. The white blood cell count is rarely elevated. The stool sodium level is usually less than 40 mEq/L. As patients become dehydrated from unreplaced fecal water loss, they may become hypertensive. The stool does not contain blood or white cells. Metabolic acidosis results from bicarbonate loss in the stool, ketosis from poor intake, and lactic acidemia from hypotension and hypoperfusion.

Replacement of fluid and electrolyte deficits and ongoing losses is critical, especially in small infants. (Oral and intravenous therapy are discussed in Chapter 43.) The use of oral rehydration fluid is appropriate in most cases. The use of clear liquids or hypocaloric (dilute formula) diets for more than 48 hours is not advisable in uncomplicated viral gastroenteritis because starvation depresses digestive function and prolongs diarrhea.

Intestinal lactase levels are reduced during rotavirus infection. Brief use of a lactose-free diet is associated with a shorter period of diarrhea but is not critical to successful recovery in healthy infants. Reduced fat intake during recovery may decrease nausea and vomiting.

Antidiarrheal medications are ineffective (kaolin-pectin combinations) or even dangerous (loperamide, tincture of opium, diphenoxylate with atropine). Bismuth subsalicylate preparations may reduce stool volume but are not critical to recovery. Oral immunoglobulin or specific antiviral agents have occasionally been useful in limiting duration of disease in immunocompromised patients.

Specific identification of rotavirus is not required in every case, especially in outbreaks. Rotavirus antigens can be identified in stool or virus can be seen by scanning electron microscopy. False-positive results (which may actually be nonpathogenic rotavirus) are seen in neonates. Most children are infected with rotavirus more than once, with the first infection being the most severe. Some protective immunity is imparted by the first infection. Prevention of infection occurs primarily by good hygiene and prevention of fecal-oral contamination. The American Academy of Pediatrics issued guidelines in January 2007 recommending the routine use of bovine-based pentavalent rotavirus vaccine to be given orally to infants at 2, 4, and 6 months of age.

2. Other Viral Infections Causing Acute Diarrhea

Other viral pathogens causing diarrhea in children can be identified in stool by electron microscopy, viral culture, or enzyme-linked immunosassay. Depending on the geographic location, enteric adenoviruses (serotypes 40 and 41) or caliciviruses are the most common viral pathogens in infants. The symptoms of enteric adenovirus infection are similar to those of rotavirus, but infection is not seasonal and duration of illness may be longer. The Norwalk agent (now called norovirus) is a calicivirus, a small RNA virus that mainly causes vomiting but can also cause diarrhea in older children and adults, usually in common source outbreaks. The duration of symptoms is short, usually 24–48 hours. Other potentially pathogenic viruses include astroviruses, corona-like viruses, and other small round viruses.

Cytomegalovirus rarely causes diarrhea in immunocompetent children but may cause erosive colitis or enteritis in immunocompromised hosts. Cytomegalovirus enteritis is particularly common after bone marrow transplantation and in late stages of HIV infection.

CHRONIC DIARRHEA

Bowel habits are variable, making specific diagnosis of chronic diarrhea difficult. Some infants normally have 5–8 stools daily. A gradual or sudden increase in the number and volume of stools to more than 15 g/kg/d combined with an increase in fluidity should raise a suspicion that an organic cause of chronic diarrhea is present. Diarrhea may result from (1) interruption of normal cell transport processes for water, electrolytes, or nutrients; (2) decrease in the surface area available for absorption secondary to shortened bowel or mucosal disease; (3) increase in intestinal motility; (4) increase in unabsorbable osmotically active molecules in the intestinal lumen; (5) increase in intestinal permeability, leading to increased loss of water and electrolytes; and (6) stimulation of entocyte secretion by toxins or cytokines. The most common entities causing chronic diarrhea are listed below. Malabsorption syndromes, which also cause chronic or recurrent diarrhea, are considered separately.

1. Noninfectious Causes of Chronic Diarrhea

A. Antibiotic Therapy

Diarrhea is reported in up to 60% of children receiving antibiotics. Only a tiny fraction of these patients have *C difficile*-related pseudomembranous enterocolitis. Eradication of normal gut flora and overgrowth of other organisms
may cause diarrhea. Most antibiotic-associated diarrhea is watery, is not associated with systemic symptoms, and decreases when antibiotic therapy is stopped.

B. Extraintestinal Infections
Infections of the urinary tract and upper respiratory tract (especially otitis media) are at times associated with diarrhea. The mechanism is obscure. Antibiotic treatment of the primary infection, toxins released by infecting organisms, and local irritation of the rectum (in patients with bladder infection) may play a role.

C. Malnutrition
Malnutrition is associated with an increased frequency of enteral infections. Decreased bile acid synthesis, decreased pancreatic enzyme output, decreased disaccharidase activity, altered motility, and changes in the intestinal flora all may cause diarrhea. Severely malnourished children are at higher risk of enteric infections because of depressed immune functions, both cellular and humoral.

D. Diet and Medications
Overfeeding may cause diarrhea, especially in young infants. Relative deficiency of pancreatic amylase in young infants causes osmotic diarrhea after starchy foods. Fruit juices, especially those high in fructose or sorbitol, produce diarrhea because these osmotically active sugars are poorly absorbed. Intestinal irritants (spices and foods high in fiber) and histamine-containing or histamine-releasing foods (eg, citrus fruits, tomatoes, fermented cheeses, red wines, and scombroid fish) also cause diarrhea.

Laxative abuse in association with eating disorders or Münchausen syndrome by proxy can cause unpredictable diarrhea. A high concentration of magnesium in the stool may indicate overuse of milk of magnesia or other magnesium-containing laxatives. Detection of other laxative preparations in the stool or circulation requires sophisticated analysis not available in most laboratories. A high index of suspicion and careful observation may be required to make this diagnosis.

E. Allergic Diarrhea
Diarrhea resulting from allergy to dietary proteins is a frequently entertained but rarely proven diagnosis. Gastrointestinal symptoms from protein allergy are more common in infants younger than age 12 months, who may experience mild to severe colitis with diarrhea and rectal bleeding in response to cow’s milk protein—either ingested directly or in minute quantities in maternal breast milk. A personal or family history of atopy is common in these infants. Skin testing is not reliable. Double-blind oral challenge with the suspected food under careful observation is necessary to confirm intestinal protein allergy. In the breast-fed infant, maternal avoidance of milk protein may be effective in reducing the signs of colitis. Substituting a protein hydrolysate formula for cow’s milk–based formula may reduce symptoms. Allergic colitis in young infants is self-limited, usually disappearing by 8–12 months of age. The condition does not require treatment if the infant is thriving and the colitic symptoms are mild. Colonoscopy is not required for diagnosis, but rectal biopsies, if performed, show mild lymphonodular hyperplasia, mucosal edema, and slight eosinophilia. Allergies to fish, peanuts, and eggs are more likely to be lifelong and more likely to be IgE mediated. Multiple food allergy (more than three) is rare.

Older children may develop a celiac-like syndrome secondary to milk protein with flattening of small bowel villi, steatorrhea, hypoproteinemia, occult blood loss, and chronic diarrhea. Skin testing is not reliable since it detects circulating antibodies, not the T-cell–mediated responses that are probably responsible for food sensitivity reactions. Double-blind oral challenge with the suspected food under careful observation is necessary to confirm intestinal protein allergy. Small bowel biopsy findings are obvious but nonspecific. The diagnosis is often confirmed by dietary trial followed by disappearance of occult blood in the stool and improvement in other symptoms.

Anaphylactic, IgE-mediated reactions to foods can occur. After ingestion, the patient quickly develops vomiting, then diarrhea, pallor, and hypotension. In these cases, skin testing is positive. Food challenges should be undertaken in a setting in which resuscitation can be performed as there is often a progressively more severe reaction with subsequent ingestions. The close association between ingestion and symptoms usually leaves little doubt about the diagnosis.

F. Chronic Nonspecific Diarrhea
Chronic nonspecific diarrhea is the most common cause of loose stools in thriving children. The typical patient is a healthy child aged 6–20 months who has three to six loose mucoid stools per day during the waking hours. The diarrhea worsens with a low-residue, low-fat, or high-carbohydrate diet and during periods of stress and infection. It clears spontaneously at about age 3½ years (usually coincident with toilet training). No organic disease is discoverable. Possible causes include abnormalities of bile acid absorption in the terminal ileum, incomplete carbohydrate absorption (excessive fruit juice ingestion seems to worsen the condition or in some cases is the primary cause), and abnormal motor function. Family history of functional bowel disease is common. Stool tests for blood, white cells, fat, parasites, and bacterial pathogens are negative.

The following measures are helpful: use of a slightly high-fat (about 40% of total calories), low-carbohydrate, high-fiber diet; avoidance of between-meal snacks; avoidance of chilled fluids, especially fruit juices. Loperamide (0.1–0.2 mg/kg/d in two or three divided doses) is often helpful. Cholestyramine (2–4 g in divided doses) or psyllium agents (1–2 tsp twice daily) are sometimes used.
6. Secretory Diarrhea

Certain malignancies of childhood (neuroblastoma, ganglioneuroma, metastatic carcinoid, pancreatic VIPoma, or gastrinoma) may secrete substances such as gastrin and vasoactive intestinal polypeptide (VIP) that promote small intestinal secretion of water and electrolytes. Children may present with large-volume, chronic and intermittent watery diarrhea that does not cease when they discontinue oral feedings. Fat malabsorption is not characteristic. The serum potassium level is often low because of stool losses. The hallmark of the diarrhea is that, unlike osmotic and infectious viral diarrhea, the sodium content of stool water is high, usually between 90 and 140 mEq/L of stool. Other signs and symptoms are associated with specific tumors. Neuroblastoma and ganglioneuroma produce elevations in urinary homovanillic acid and vanillylmandelic acid. Metastatic carcinoid produces characteristic flushing and sweating. Gastrinoma may produce multiple duodenal ulcers (Zollinger-Ellison syndrome).

In all secretory diarrheas, a careful radiologic search for a tumor is indicated. Intraendoscopic ultrasound examination may reveal small tumors in the bowel wall or pancreatic head. Bacterial overgrowth of the small bowel in patients with short bowel, cancer chemotherapy, or anatomic abnormalities may be associated with enterotoxins that promote secretory diarrhea. Cholera is the best known bacterial secretory diarrhea. Its enterotoxin stimulates cyclic adenosine monophosphate in the enterocyte, which promotes salt and water secretion.

2. Infectious Causes of Chronic Diarrhea

Most infections of the GI tract are acute and resolve spontaneously or with specific antibiotic therapy. Organisms most prone to cause chronic or recurrent diarrhea in immunocompetent children are Giardia lamblia, Entameba histolytica, Salmonella spp, and Yersinia.

Chronic diarrhea is common in immune deficiency states, especially IgA deficiency and T-cell abnormalities. The cause of is often common bacterial, viral, fungal, or parasitic organisms usually considered nonpathogenic (rotavirus, Blastocystis hominis, Candida), or unusual organisms (cytomegalovirus, Cryptosporidium, Isospora belli, Mycobacterium spp, microsporidia, and algal organisms such as cyanobacteria).

Between 50% and 60% of patients with idiopathic acquired hypogammaglobulinemia have steatorrhea and intestinal villous atrophy. Lymphonodular hyperplasia of the small intestine is prominent. Patients with congenital or Bruton-type agammaglobulinemia usually have diarrhea and abnormal intestinal morphology. Patients with isolated IgA deficiency have chronic diarrhea, a celiac-like picture, lymphoid nodular hyperplasia, and are prone to giardiasis. Patients with isolated cellular immunity defects, combined cellular and humoral immune incompetence, and HIV infection may have severe chronic diarrhea leading to malnutrition. Often the cause is not found. The incidence of disaccharidase deficiency is high. Chronic granulomatous disease may be associated with intestinal symptoms suggestive of chronic inflammatory bowel disease. A rectal biopsy may reveal the presence of typical macrophages.

Treatment must be directed toward correcting the immunologic defect. Specific treatments are available or are being developed for many of the unusual pathogens causing diarrhea in the immunocompromised host. Thus, a vigorous diagnostic search for specific pathogens is warranted in these individuals.

GASTROINTESTINAL BLEEDING

Vomiting blood and passing blood per rectum are alarming symptoms. The history is the key to identifying the bleeding source. The following questions should be answered:

1. Is it really blood, and is it coming from the GI tract? A number of substances simulate hematochezia or melena (Table 20–5). The presence of blood should be confirmed chemically. Coughing, tonsillitis, lost teeth, or epistaxis may cause what appears to be occult or overt GI bleeding. An adolescent female may be experiencing menarche.

Table 20–5. Pitfalls in the diagnosis of gastrointestinal bleeding in children.

\(^d\)High false-positive rate with orthotoluidine-based tests.

2. How much blood is there and what is its color and character? Table 20–6 lists the sites of GI bleeding predicted by the appearance of the blood in the stools. Table 20–7 lists causes of rectal bleeding.

3. Is the child acutely or chronically ill? The physical examination should be thorough. Physical signs of portal hypertension, intestinal obstruction, or coagulopathy are particularly important. The nasal passages should be inspected for signs of recent epistaxis, the vagina for menstrual blood, and the anus for fissures and hemorrhoids. A systolic blood pressure below 100 mm Hg and a pulse rate above 100 beats/min in an older child suggest at least a 20% reduction of blood volume. A pulse rate increase of 20 beats/min or a drop in systolic blood pressure greater than 10 mm Hg when the patient sits up is also a sensitive index of volume depletion.

4. Is the child still bleeding? Serial determination of vital signs and hematocrit are essential to assess ongoing bleeding. Detection of blood in the gastric aspirate confirms a bleeding site proximal to the ligament of Treitz. However, its absence does not rule out the duodenum as the source. Testing the stool for occult blood will help in monitoring ongoing loss of blood.

**Treatment**

If a hemorrhagic diathesis is detected, vitamin K should be given intravenously. In severe bleeding, the need for volume replacement is monitored by measurement of central venous pressure. In less severe cases, vital signs, serial hematocrits, and gastric aspirates are sufficient.

If blood is recovered from the gastric aspirate, gastric lavage with saline should be performed until only a blood tinged return is obtained. Upper intestinal endoscopy is then done to identify the bleeding site. Endoscopy is superior to barium contrast study for lesions such as esophageal varices, stress ulcers, and gastritis. Colonoscopy may identify the source of bright red rectal bleeding but should be performed as an emergency procedure only if the extent of bleeding warrants immediate investigation and if plain abdominal radiographs show no signs of intestinal obstruction. Colonoscopy on an unprepped colon is often inadequate for making a diagnosis. Capsule endoscopy may help identify the site of bleeding if colonoscopy and upper endoscopy findings are negative. Small or large bowel lesions that bleed briskly (> 0.5 mL/min) may be localized by angiography or radionuclide scanning following injection of labeled red cells.

Persistent vascular bleeding (varices, vascular anomalies) may be relieved temporarily using intravenous octreotide, 25–30 μg/m²/h. Sustained infusion of octreotide may be used for up to 48 hours if needed. Bleeding from esophageal varices may be stopped by compression with a Sengstaken-Blakemore tube. Endoscopic sclerosis or banding of bleeding varices is effective treatment.

If gastric decompression, acid suppressive therapy, and transfusion are ineffective in stopping ulcer bleeding, laser therapy, local injection of epinephrine, electrocautery, or emergency surgery may be necessary.

**VOMITING**

Vomiting is an extremely complex, poorly understood activity. The centers controlling and coordinating vomiting are in the paraventricular nuclei of the brain. These nuclei receive afferent input from many sources: drugs and neurotransmitters in cerebrospinal fluid, the chemoreceptor trigger zone (CTZ) near the distal fourth ventricle, the vestibular apparatus of the ear, the GI tract and other abdominal organs, and even from higher cortical areas. Vagal afferents from gut to brain are stimulated by ingested drugs and toxins, mechanical stretch, inflammation, and local neurotransmitters. Additionally, local feedback loops in the gut also appear capable of initiating vomiting.

Vomiting is the presenting symptom of many pediatric conditions. It is the pediatrician’s difficult job to find the underlying cause. The most common cause of vomiting in childhood is probably acute viral gastroenteritis. However, obstruction and acute or chronic inflammation of the GI tract and associated structures are also major causes. Central nervous system inflammation, pressure, or tumor may cause vomiting. Metabolic derangements associated with inborn errors of metabolism, sepsis, and drug intoxication can stimulate either the CTZ or the brain directly to promote vomiting.
Regurgitation associated with GE reflux of infants should be distinguished from vomiting. In this instance, spontaneous relaxation of the lower esophageal sphincter creates a common cavity between the stomach and esophagus. Because the resting pressure of the thorax is negative, the mildly positive pressure of the abdominal cavity (~6 mm Hg) pushes gastric contents into the esophagus, causing an effortless flow into the mouth. Occasionally, regurgitated fluid stimulates the pharyngeal afferents and provokes gagging or even a complete vomiting complex.

Control of vomiting with medication is rarely needed in acute gastroenteritis and should not be attempted in other patients until the source is clear. Antihistamines and anticholinergics are appropriate for motion sickness because of their labyrinthine effects. 5-HT₃ receptor antagonists (ondansetron, granisetron) are useful for vomiting associated with surgery and chemotherapy. Benzodiazepines, corticosteroids, and substituted benzamides are also used in chemotherapy-induced vomiting. Butyrophenones (droperidol, haloperidone) are powerful drugs that block
the D2 receptor in the CTZ and are used for intractable vomiting in acute gastritis, chemotherapy, and after surgery. Phenothiazines are helpful in chemotherapy, cyclic vomiting, and acute GI infection but are not recommended for outpatient use because of extrapyramidal side effects.

1. Cyclic Vomiting Syndrome

Clinical Findings

Cyclic vomiting syndrome (CVS) is characterized by recurrent episodes of stereotypical vomiting in children usually older than 1 year of age. The emesis is forceful and frequent, occurring up to six times per hour for up to 72 hours or more. Episode frequency ranges from two to three per month to less than one per year. Nausea, retching, and small-volume bilious emesis continue even after the stomach is emptied. Hematemesis secondary to forceful vomiting may occur. Patients experience abdominal pain, anorexia, and rarely, diarrhea. Autonomic symptoms, such as pallor, sweating, temperature instability, and lethargy are common and give the patient a very ill appearance. The episodes end suddenly, often after a period of sleep. In some children, dehydratation, electrolyte imbalance, and shock may occur. Between episodes, the child is completely healthy.

The cause of CVS is unknown; however, a similarity to migraine has long been recognized. Family history is positive for migraine in 50–70% of cases and many patients develop migraine headaches as adults. Research suggests that abnormalities of neurotransmitters and hormones provoke CVS. About one quarter of patients have typical migraine symptoms during episodes: premonitory sensation, headache, photophobia, and phonophobia. Identifiable triggers include infection, positive or negative emotional stress, diet (chocolate, cheese, monosodium glutamate), menses, or motion sickness.

Differential Diagnosis

Conditions that mimic CVS include drug toxicity, increased intracranial pressure, seizures, brain tumor, Chiari malformation, recurrent sinusitis, choledochal cyst, gallstones, recurrent small bowel obstruction, inflammatory bowel disease, familial pancreatitis, obstructive uropathy, recurrent urinary infection, diabetes, mitochondrial diseases, disorders of fatty and organic acid metabolism, adrenals insufficiency, and Münchausen syndrome by proxy. Although tests for GE reflux are often positive in these patients, it is unlikely that GE reflux and CVS are related.

Treatment

Avoidance of triggers prevents spells in some patients. Sleep can also end a spell although some children awaken and resume vomiting. Diphenhydramine or lorazepam are used at the onset of spells in some children to reduce nausea and induce sleep. Early use of antimigraine medications (sumatriptan), antiemetics (ondansetron), or antihistamines can abort spells in some patients. Once a spell is well established, intravenous fluids are often required to end it. With careful supervision, some children with predictable spells can receive intravenous fluids at home. Several approaches are tried before an effective therapy is found. Preventing spells with prophylactic propranolol, amitriptyline, or antihistamines is effective in some patients with frequent or disabling spells. Some patients have been successfully treated with anticonvulsants.

RECURRENT ABDOMINAL PAIN

About 10% of healthy schoolchildren between 5 and 15 years of age will at some time have recurrent episodes of unexplained abdominal pain severe enough to interfere with normal activities. An organic cause is found in fewer than 10% of patients.

Clinical Findings

A. Symptoms and Signs

Attacks of pain are characteristically of variable duration and intensity. It is not rare for the parent or patient to report that the pain is constant, all day, every day. Although the pain is usually located in the periumbilical area, a location far from the umbilicus does not rule out recurrent abdominal pain. Pain occurs both day and night. Weight loss is rare. Pain may be associated with dramatic reactions—frantic crying, clutching the abdomen, doubling over. Parents may be alarmed, and children are often taken to emergency departments, where the evaluation is negative for an abdominal crisis. School attendance may suffer, and enjoyable family events may be disrupted. The pain may be associated with pallor, nausea, vomiting, and slight temperature elevation.

The pain usually bears little relationship to bowel habits and physical activity. However, some patients have a symptom constellation suggestive of irritable bowel syndrome—bloating, postprandial pain, lower abdominal discomfort, and erratic stool habits with a sensation of obstruction or incomplete evacuation of stool. A precipitating or stressful situation in the child’s life at the time the pains began can sometimes be elicited. School phobia may be a precipitant. A history of functional GI complaints is often found in family members. A thorough physical examination is essential and usually normal. Complaints of abdominal tenderness elicited during palpation sometimes seem out of proportion to visible signs of distress.

B. Laboratory Findings

Complete blood count, sedimentation rate, urinalysis, and stool test for occult blood usually suffice. In the adolescent female patient, ultrasound of the abdomen may be helpful to detect gallbladder or ovarian pathology. If the pain is atypi-
Incarcerated hernia
Distal intestinal obstruction
Midgut volvulus
Testicular torsion
esophagitis, duodenitis, and ulcer disease is probably under-associated with vomiting. The incidence of peptic gastritis, epilepsy are rare conditions with an episodic character often the only symptom. Abdominal migraine and abdominal ingestion. At times, however, abdominal discomfort may be cause of recurrent abdominal pain. Lactose intolerance usu-
medications are rarely helpful and should be reserved for those with what appears to be visceral hyperalgesia, amitriptyline in low doses may occasionally be helpful. Antispasmodic required, but drugs should be avoided. In older patients, and in attendance. Therapy for emotional problems is sometimes helpful. Regular activity should be resumed, especially school child’s complaints. Reassurance without education is rarely helpful. Regular activity should be resumed, especially school attendance. Therapy for emotional problems is sometimes required, but drugs should be avoided. In older patients, and in those with what appears to be visceral hyperalgesia, amitriptyline in low doses may occasionally be helpful. Antispasmodic medications are rarely helpful and should be reserved for patients with more typical irritable bowel complaints.

Differential Diagnosis
Abdominal pain secondary to disorders causing acute abdo-
men are listed in Table 20–8. Pinworms, mesenteric lymphadenitis, and chronic appendicitis are improbable causes of recurrent abdominal pain. H pylori infection is rarely the cause of recurrent abdominal pain. Lactose intolerance usually causes abdominal distention, gas, and diarrhea with milk ingestion. At times, however, abdominal discomfort may be the only symptom. Abdominal migraine and abdominal epilepsy are rare conditions with an episodic character often associated with vomiting. The incidence of peptic gastritis, esophagitis, duodenitis, and ulcer disease is probably under-appreciated. Upper intestinal endoscopy may be useful.

Treatment & Prognosis
Treatment consists of reassurance based on a thorough physical appraisal and a sympathetic, age-appropriate explanation of the nature of functional pain. The concept of “visceral hyperalgesia” or increased pain signaling from physiologic stimuli such as gas, acid secretion, or stool is one that parents can understand and helps them to respond appropriately to the child’s complaints. Reassurance without education is rarely helpful. Regular activity should be resumed, especially school attendance. Therapy for emotional problems is sometimes required, but drugs should be avoided. In older patients, and in those with what appears to be visceral hyperalgesia, amitriptyline in low doses may occasionally be helpful. Antispasmodic medications are rarely helpful and should be reserved for patients with more typical irritable bowel complaints.

ACUTE ABDOMEN
An acute abdomen is a constellation of findings indicating an intra-abdominal process that may require surgery. A degree of urgency is implied when this diagnosis is suspected. The pain of an acute abdomen intensifies over time and is rarely relieved without definitive treatment. Pain is often accompanied by nausea, vomiting, diarrhea, fever, and anorexia. Pain may be localized or generalized. The abdomen may be distended and tense and bowel sounds reduced or obstructive. Patients appear ill and are reluctant to be examined or moved. The acute abdomen is usually a result of infection of the intra-abdominal or pelvic organs but also occurs with intestinal obstruction, intestinal perforation, inflammatory conditions, trauma, and some metabolic disorders. Some conditions causing acute abdomen are listed in Table 20–8. Reaching a speedy and accurate diagnosis is critical and requires skill in physical diagnosis, recognition of the symptoms of a large number of conditions, and a judicious selection of laboratory and radiologic tests. (Acute appendicitis is discussed earlier in the section on Disorders of the Small Intestine.)

MALABSORPTION SYNDROMES
Malabsorption of ingested food has many causes (Table 20–9). Shortening of the small bowel (usually via surgical resection) and mucosal damage (celiac disease) both reduce surface area. Impaired motility of the small intestine may interfere with normal propulsive movements and mixing of food with pancreatic and biliary secretions. Anaerobic bacteria proliferate under these conditions and impair fat absorption by deconjugation of bile acids (intestinal pseudo-obstruction, postoperative blind loop syndrome). Impaired intestinal lymphatic (congenital lymphangiectasia) or venous drainage also causes malabsorption. Diseases reducing pancreatic exocrine function (cystic fibrosis, Shwachman syndrome) or the production and flow of biliary secretions cause nutrient malabsorption. Malabsorption of specific nutrients may be genetically determined (disaccharidase deficiency, glucose-galactose malabsorption, and abetalipoproteinemia).

Clinical Findings
Diarrhea, vomiting, anorexia, abdominal pain, failure to thrive, and abdominal distention are common. Stool may be bulky, foul, and pale with fat malabsorption or loose when diarrhea is osmotically induced. Microscopic examination of stools for neutral fat and fatty acids is a useful screen because most malabsorption syndromes involve some fat malabsorption. Pancreatic insufficiency is associated with neutral fat (triglycerides) in the stool. Fatty acids are the major fatty material found in the stool of patients with mucosal and liver disease.

Quantitation of fat malabsorption requires measuring fat excreted in the feces as a proportion of fat intake for a defined
period. Excretion of 5% of ingested fat is normal for a child older than age 1 year; 10–15% is normal in a younger infant. Prothrombin time and serum carotene, vitamin E, and vitamin D levels may be depressed by long-standing fat malabsorption. Accurate assessment of protein absorption is difficult and requires isotopic labeling of amino acids. Loss of serum proteins across the intestinal mucosa can be estimated by measurement of fecal α₁-antitrypsin. Malabsorption of complex carbohydrate is rarely measured. Disaccharide or monosaccharide malabsorption is estimated by reduction in stool pH, increased breath hydrogen after ingestion of carbohydrate, or decreased intestinal mucosal disaccharidase activity.

Other screening tests suggesting a specific diagnosis include sweat chloride concentration (cystic fibrosis), intestinal mucosal biopsy (celiac disease, intestinal lymphangiectasia, giardiasis, inflammatory bowel disease), liver and gallbladder function tests, and pancreatic secretion after stimulation with secretin and cholecystokinin. Some of the most common disorders associated with malabsorption in pediatric patients are detailed below.

1. **Protein-Losing Enteropathy**

Loss of plasma proteins into the GI tract occurs in association with intestinal inflammation, intestinal graft-versus-host disease, acute and chronic intestinal infections, venous and lymphatic obstruction or malformations, and infiltration of the intestine or its lymphatics and vasculature by malignant cells. Chronic elevation of venous pressure in children with the Fontan procedure may produce protein-losing enteropathy.

### Clinical Findings

Signs and symptoms are mainly those caused by hypoproteinemia, and in some instances by fat malabsorption: edema, ascites, poor weight gain, and specific vitamin and mineral deficiencies. Serum albumin and globulins may be decreased. Fecal α₁-antitrypsin is elevated (> 3 mg/g dry weight stool; slightly higher in breast-fed infants). Disorders associated with protein-losing enteropathy are listed in Table 20–10. In the presence of intestinal bleeding, fecal α₁-antitrypsin measurements are falsely high.

### Differential Diagnosis

Hypoalbuminemia may be due to increased catabolism, poor protein intake, impaired hepatic protein synthesis, or congenital malformations of lymphatics outside the GI tract. Protein losses in the urine from nephritis and nephrotic syndrome may also cause hypoalbuminemia.

Children who undergo Fontan procedure for tricuspid atresia are especially prone.
CHAPTER 20

Treatment

Albumin infusion, diuretics, and a high-protein, low-fat diet may control symptoms. Treatment must be directed toward identifying and treating the underlying cause.

2. Celiac Disease (Gluten Enteropathy)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Diarrhea, fatty stools, failure to thrive, irritability, hypoproteinemia, edema.
- Mean age of onset is 18 months.
- Tissue transglutaminase antibody testing is positive.
- Intestinal biopsy confirms the diagnosis.

Celiac disease results from intestinal sensitivity to the gliadin fraction of glutens from wheat, rye, barley, and (possibly) oats. Most children present during the second year of life, but the age at onset and the severity are variable. Up-to-date estimates of disease frequency are being revised with the widespread use of sensitive screening tests such as the tissue transglutaminase. Screening with antigliadin antibodies is not recommended because of the high frequency of false-positive tests. The frequency of celiac disease in the United States is around 1:300. It is thought that intestinal damage and villous atrophy result from a cell-mediated immune response initiated by exposure to a polypeptide fragment of gliadin. Ten percent of first-degree relatives may be affected. The inheritance is probably polygenic but may result from a single gene in combination with an environmental precipitant such as intestinal viral infection. The increased incidence of celiac disease in children with type 1 diabetes mellitus, IgA deficiency, and Down syndrome is consistent with possible immunologic factors in the development of celiac disease. Individuals with HLA DR4 and perhaps DR3 tissue types are at higher risk.

Clinical Findings

A. Symptoms and Signs

1. Diarrhea—Affected children usually have diarrhea starting 6–12 months after the introduction of grains. Initially, the diarrhea may be intermittent; subsequently it is continuous, with bulky, pale, frothy, greasy, foul-smelling stools. During celiac crises, dehydration, shock, and acidosis occur. If anorexia is severe (about 10% of cases), diarrhea may be absent.

2. Constipation, vomiting, and abdominal pain—This triad of symptoms may occasionally dominate the clinical picture and suggest a diagnosis of intestinal obstruction. Constipation generally results from a combination of anorexia, dehydration, muscle weakness, and bulky stools.

3. Failure to thrive—Active celiac disease is often accompanied by loss of appetite, failure to gain weight, and irritability. Weight loss is most marked in the limbs and buttocks. The abdomen becomes distended secondary to intestinal gas and fluid accumulation. Short stature and delayed puberty may be the only sign in some older children.

4. Anemia and vitamin deficiencies—Anemia usually responds to iron supplementation and is rarely megaloblastic. Anemia is a more common presenting problem in adults than in children. Fat-soluble vitamin deficiency is common. Rickets can be seen in growing children but osteomalacia even with pathologic fractures is more common. Hypoprothrombinemia secondary to vitamin K malabsorption can cause easy bleeding.

5. Silent celiac disease—Serologic screening in children with nonspecific GI complaints, growth failure, type 1 diabetes, thyroid disease, vitiligo, IgA deficiency, and Down syndrome, and in family members of celiac patients is widespread. The therapy for a symptom-free child with positive serology is unclear. Intestinal biopsy specimens from children with positive serology are usually abnormal and the prudent response is to recommend a gluten-free diet. In patients with positive serology but normal intestinal biopsies, careful follow-up without diet therapy is the most appropriate current recommendation.

B. Laboratory Findings

1. Fat content of stools—A 3-day collection of stools usually reveals excessive fecal fat excretion. A normal child excretes 5–10% of ingested fat. In untreated celiac disease fat excretion is more than 15% of daily fat intake. Anorexia may be so severe that steatorrhea may not be present in 10–25% of patients until normal intake is established.

2. Carbohydrate absorption—A low oral glucose tolerance curve is seen. Absorption of D-xylose is impaired, with blood levels lower than 20 mg/dL 60 minutes after ingestion.

3. Hypoproteinemia—Hypoalbuminemia can be severe enough to lead to edema. There is evidence of increased protein loss in the gut lumen and poor hepatic synthesis secondary to malnutrition.

4. Serologic and genetic testing—The most sensitive and specific screening test for celiac disease in IgA-sufficient patients is a tissue transglutaminase antibody test. In the presence of IgA deficiency, this test may be falsely negative. IgG tissue transglutaminase antibody testing is available. The tissue transglutaminase antibody results can be used to roughly gauge dietary compliance. Antigliadin antibodies are not reliable for screening. Genetic screening for typical tissue type may be an indication of risk but it is not diagnostic.

C. Imaging

A small bowel series shows a malabsorptive pattern characterized by segmentation, clumping of the barium column,
and hypersecretion. These changes are nonspecific and can be found in patients with other malabsorption states.

D. Biopsy Findings

Intestinal biopsy is the most reliable test for celiac disease. By light microscopy, the celiac mucosa has shortened or absent villi, lengthened crypts of Lieberkühn, intense plasma cell infiltration of the lamina propria, and numerous intraepithelial lymphocytes. Extent of change is quantitated from 0 (normal) to 4 (complete villous atrophy) using the Marsh scoring system.

Differential Diagnosis

The differential diagnosis includes disorders causing malabsorption. Strict adherence to two diagnostic criteria is essential—the characteristic small bowel microscopic changes and clinical improvement on a gluten-free diet. Repeat mucosal biopsies to prove histologic recovery on gluten-free diet and relapse on gluten challenge are not indicated in typical patients.

Treatment

A. Diet

Treatment is dietary gluten restriction for life. All sources of wheat, rye, and barley are eliminated. Some patients can tolerate oats, but this should be tested only after recovery has occurred. Lactose is poorly tolerated in the acute stage because mucosal atrophy causes secondary disaccharidase deficiency. Normal amounts of fat are advisable. Supplemental calories, vitamins, and minerals are indicated only in the acute phase. Clinical improvement usually starts within a week, but complete clinical recovery and histologic normality may require 3–12 months. Tissue transglutaminase titers may decrease on a gluten-free diet, but usually do not disappear.

B. Corticosteroids

Corticosteroids can hasten clinical improvement but are indicated only in very ill patients with profound anorexia, malnutrition, diarrhea, edema, abdominal distention, and hypokalemia.

Prognosis

Clinical and histologic recovery is the rule but may be slow. Malignant lymphoma of the small bowel occurs with increased frequency in adults with long-standing disease. Dietary treatment seems to decrease the risk of this complication.

3. Disaccharidase Deficiency

Starches and the disaccharides sucrose and lactose are the most important dietary carbohydrates. Dietary disaccharides and oligosaccharide products of pancreatic amylase action on starch require hydrolysis by intestinal brush border disaccharidases before absorption takes place. Disaccharidase levels are higher in the jejunum and proximal ileum than in the distal ileum and duodenum. In primary disaccharidase deficiency, a single enzyme is affected; disaccharide intolerance is permanent; intestinal histologic findings are normal; and a positive family history is common. Because disaccharidases are located on the luminal surface of intestinal enterocytes, they are susceptible to mucosal damage. Many conditions cause secondary disaccharidase deficiency and lactase is usually the most severely depressed.

A. Lactase Deficiency

Congenital lactase deficiency is rare. All human ethnic groups are lactase-sufficient at birth. Genetic or familial lactase deficiency begins to appear in children as young as 3–5 years. In Asians, Alaskan natives, and Native Americans, genetic lactase deficiency develops in virtually 100%. In Africans, the incidence in most tribes is over 80%. In African Americans, the incidence is about 70%, and among Caucasian Americans, the incidence is between 30% and 60%. Acquired or secondary lactase deficiency caused by intestinal injury due to viral infection, inflammatory disease, radiation, and drugs is very common. Lactase deficiency secondary to viral gastroenteritis is usually self-limited, lasting days or, at most, weeks after recovery from infection. Lactose ingestion in deficient individuals causes variable degrees of diarrhea, gassy distention, and abdominal pain depending on the residual enzyme activity and the dose of lactose. Stools are liquid or frothy, with a pH below 4.5 owing to the presence of organic acids. Vomiting is common. Severe malnutrition may occur in a milk-fed infant with lactase deficiency. Reducing substances are present in fresh stools. The blood glucose fails to rise more than 10 mg/dL after ingestion of 1 g/kg of lactose. A rise in breath hydrogen after oral administration of lactose (from hydrogen produced by normal colon flora during fermentation of unabsorbed carbohydrate) is also diagnostic.

Symptoms disappear when dietary lactose is restricted. Lactase extracted from Aspergillus and Kluyvera species can be added to milk products or taken with meals to enhance lactose hydrolysis.

B. Sucrase-Isomaltase Deficiency

This is a combined defect inherited as an autosomal recessive trait. Ten percent of Alaskan natives are affected. The condition is rare in other groups. Abdominal distention, failure to thrive, and chronic diarrhea may be the presenting symptoms. Intestinal mucosal damage from viral infection reduces the activity of all disaccharidases including sucrase,
but symptoms of sucrose intolerance are usually masked by the more striking symptoms of lactose intolerance. Distaste for and avoidance of sucrose occurs even in young infants with genetic sucrase-isomaltase deficiency.

Because sucrose is not a reducing sugar, the results of tests for reducing substances in the stool are negative unless the sucrose in the stool is hydrolyzed by colon bacteria. Oral sucrose tolerance testing (1 g/kg) is abnormal. Breath hydrogen will be elevated after ingestion of sucrose. Treatment of primary sucrase-isomaltase deficiency requires elimination of most sucrose. A preparation of yeast sucrase taken with meals is also effective.

4. Glucose-Galactose Malabsorption

Glucose-galactose malabsorption is a rare disorder in which the sodium-gluconate transport protein is defective. The gene has been localized to the long arm of chromosome 22. Transport of glucose in the intestinal epithelium and renal tubule is impaired. Diarrhea begins with the first feedings, accompanied by reducing sugar in the stool and acidosis. Small bowel histologic findings are normal. Glycosuria and aminoaciduria may occur. The glucose tolerance test is flat. Fructose is well tolerated. Diarrhea subsides promptly on withdrawal of glucose and galactose from the diet. The acquired form of glucose-galactose malabsorption occurs mainly in infants younger than age 6 months, usually following acute viral or bacterial enteritis.

In the congenital disease, exclusion of glucose and galactose from the diet is mandatory. A satisfactory formula is one with a carbohydrate-free base plus added fructose. The prognosis is good if the disease is diagnosed early, because tolerance for glucose and galactose improves with age. In secondary monosaccharide intolerance, prolonged parenteral nutrition may be required until intestinal transport mechanisms for monosaccharides return.

5. Intestinal Lymphangiectasia

This form of protein-losing enteropathy results from a congenital ectasia of the bowel lymphatic system, often associated with abnormalities of the lymphatics in the extremities. Obstruction of lymphatic drainage of the intestine leads to rupture of the intestinal lacteals with leakage of lymph into the lumen of the bowel. Fat loss in the stool may be significant. Chronic loss of lymphocytes and immunoglobulins increases the susceptibility to infections.

6. Cow’s Milk Protein Intolerance

Milk protein intolerance is more common in males than females and in young infants with a family history of atopy. The estimated prevalence is 0.5–1.0%. Colic, vomiting, and diarrhea are the major symptoms in young infants whose stools often contain small flecks of blood and mucus. Children with these symptoms are generally healthy and gain weight normally. The diagnosis is usually made clinically. Elimination of whole milk from the maternal diet sometimes relieves symptoms. A switch to a protein hydrolysate formula almost always results in improvement. Because the blood loss and diarrhea are rarely severe, it is not essential that breast feeding be stopped. If symptoms are severe or prolonged, a trial of semielemental formula is recommended. Allergic colitis in infants usually clears spontane-
ously by age 6–12 months. When there is uncertainty or when symptoms are severe, sigmoidoscopic examination reveals a superficial colitis, often with edema, a mild eosinophilic infiltrate, and lymphonodular hyperplasia. Pneumato-
sis intestinalis rarely is found on radiographs. Viral gastroenteritis sometimes precedes the onset of symptoms. Early reports that patients with milk protein allergy have a 30% incidence of sensitivity to soy protein, with similar symp-
toms, have not been uniformly confirmed.

In older children, milk protein sensitivity may induce eosinophilic gastroenteritis with protein-losing enteropathy, iron deficiency, hypoalbuminemia, and hypogammaglobulinemia. A celiac-like syndrome with villous atrophy, malab-
sorption, hypoalbuminemia, occult blood in the stool, and anemia can occur.

IgE-mediated anaphylactic shock is a rare but potentially life-threatening manifestation of milk protein sensitivity in infancy. If the symptoms suggest an anaphylactic response to milk or other protein, food challenge should be performed only in a setting in which resuscitation can be carried out.

7. Pancreatic Insufficiency
The most common cause of pancreatic exocrine insuffi-
ciency in childhood is cystic fibrosis. Decreased secretion of pancreatic digestive enzymes is caused by obstruction of the exocrine ducts by thick secretions, which destroys pancreatic acinar cells. Destruction of acinar cells may occur antenatally. Some genotypes of cystic fibrosis have partially or completely preserved pancreatic exocrine function. Other conditions associated with exocrine pancreatic insufficiency are discussed in Chapter 21.

8. Other Genetic Disorders Causing Malabsorption
A. Abetalipoproteinemia
Abetalipoproteinemia is an autosomal recessive condition in which the secretion of triglyceride-rich lipoproteins from the small intestine (chylomicrons) and liver (very low-density lipoproteins) is abnormal. Profound steatosis of the intestinal enterocytes (and hepatocytes) and severe fat malabsorption occur. Deficiencies of fat-soluble vitamins develop with neurologic complications of vitamin E deficiency and atypical retinitis pigmentosa. Serum cholesterol level is very low, and red cell membrane lipids are abnormal, causing acanthosis of red blood cells, which may be the key to diagnosis.

B. Acrodermatitis Enteropathica
Acrodermatitis enteropathica is an autosomal recessive condition in which the intestine has a selective inability to absorb zinc. The condition usually becomes obvious at the time of weaning and is characterized by rash on the extremities, rashes around the body orifices, eczema, profound failure to thrive, steatorrhea, diarrhea, and immune deficiency. Zinc supplementation by mouth results in rapid improvement.

INFLAMMATORY BOWEL DISEASE

General Considerations
Inflammatory bowel disease is most commonly differenti-
ated into Crohn disease (CD) and ulcerative colitis (UC). The etiology is most likely multifactorial, involving a com-
plex interaction of immune, environmental (eg, smoking, breast feeding, diet), and genetic factors. The genetic associa-
tion is clear, with frequency as high as 40% in first-degree relatives. Monozygotic twins have a 37% concordance for CD and 10% concordance for UC. Mutations in the NOD2/ CARD15 gene on chromosome 16 have been implicated in CD. This gene has an important role in activating nuclear factor-κ, which mediates the inflammatory response and the production of proinflammatory cytokines.

Clinical Findings
A. Symptoms and Signs
The clinical presentation of inflammatory bowel disease depends on the site of inflammation. Most (50–70%) children with CD have terminal ileal disease, and more than half have colonic involvement, typically of the ascending colon. Ten to 20% have isolated colonic disease, and 10–15% have small bowel disease. Gastroduodenal inflammation is common, although isolated gastric disease is rare. CD patients may have nonspecific symptoms at presentation, leading to delays in diagnosis. The most common presentation is abdominal pain, sometimes with diarrhea and weight loss. Some patients may have anal skin tags or fistulas on examination. Rectal bleeding and nonspecific symptoms such as fever, anorexia, fatigue, nausea and vomiting, aphthous ulcerations, short stature, and delayed puberty may also occur.

The most common symptoms in UC are rectal bleeding, diarrhea, and abdominal pain. In contrast to CD, the colon is the major site of inflammation with 44–49% of patients having rectosigmoid disease; 36–41%, left-sided colonic dis-
 ease; and 14–37%, pancolitis. The younger the child, the more aggressive the inflammatory process is likely to be.

Extraintestinal symptoms and signs are common in both CD and UC and may precede the onset of GI symptoms. Arthritis is the most common extraintestinal manifestation of inflamma-
tory bowel disease. Nephrolithiasis, erythema nodosum, and pyoderma gangrenosum can also occur. Uveitis, conjunctivitis, and primary sclerosing cholangitis may also be seen.

B. Diagnostic Testing
Patients with inflammatory bowel disease often have low hemoglobin and serum albumin levels and increased platelet
count, erythrocyte sedimentation rate, and C-reactive protein. These findings are not always present. Serum antibodies to Saccharomyces cerevisiae (ASCA) are detected in 40–60% of patients with CD. Serum perinuclear antineutrophil cytoplasmic antibodies (pANCA) are present in approximately 70% of UC patients. Both of these antibodies, if positive, may be helpful screens, but they are neither sensitive nor specific enough to be diagnostic. In patients with diarrhea, it is important to evaluate for infectious and malabsorptive problems.

Barium upper GI study with small bowel follow-through shows small bowel disease. CT scan and magnetic resonance imaging may show mucosal and mural edema but are not specific. Intestinal wall thickening is often reported on CT scans performed as part of an urgent evaluation to rule out appendicitis. This finding is probably an acute reaction to infection and should not prompt an extensive evaluation for CD without other supporting symptoms or signs.

Upper endoscopy and colonoscopy including the terminal ileum are essential in diagnosing inflammatory bowel disease. Mucosal involvement in CD is typically patchy with disease-free skip areas. It can be found in any part of the GI tract (including esophagus and stomach) with transmural inflammation manifested by ulcers, fistulas, strictures, and granulomas. UC is usually localized to the colon, and generally the inflammation is mucosal or submucosal. Although inflammation seems to spread proximally from the rectum, rectal sparing sometimes occurs.

Differential Diagnosis

When extraintestinal symptoms predominate, CD can be mistaken for rheumatoid arthritis, systemic lupus erythematosus, or hypopituitarism. The acute onset of ileocolitis may be mistaken for appendicitis. Symptoms sometimes suggest celiac disease, peptic ulcer, intestinal obstruction, intestinal lymphoma, anorexia nervosa, or growth failure from endocrine causes. In the acute stage, bacterial pathogens and toxins causing colitis must be ruled out. These include Shigella, Salmonella, Yersinia, Campylobacter, Entamoeba histolytica, enteroinvasive Escherichia coli (E coli O157), Aeromonas hydrophila, Giardia, and Clostridium difficile. Mild UC sometimes mimics irritable bowel syndrome. Eosinophilic gastroenteropathy and vasculitic lesions should also be considered. Finally, Behçet disease should be considered. It is characterized by oral aphthous ulcerations along with at least two of the following: genital ulcers, synovitis, posterior uveitis, meningoencephalitis, and pustular vasculitis. Patients with Behçet disease also may have anorexia, vomiting, diarrhea, abdominal pain, distention, and dyspepsia.

Complications

A. Crohn Disease

Malnutrition is caused by anorexia and compounded by malabsorption, protein-losing enteropathy, iron-deficiency anemia, disaccharidase deficiency, and bile salt malabsorption in poorly controlled disease. Growth failure, delayed bone age, and delayed puberty are common results of malnutrition and steroid use. Controlling active disease to the point of remission usually allows for improved nutrition and resumption of normal growth velocity. Most patients today achieve reasonable final adult height. Intestinal obstruction, fistulae, abdominal abscess, perianal disease, pyoderma gangrenosum, arthritis, and amyloidosis occur. The risk of colon cancer is increased in patients with CD colitis although not to the extent seen in UC.

B. Ulcerative Colitis

Arthritis, uveitis, pyoderma gangrenosum, and malnutrition all occur. Growth failure and delayed puberty are less common than in CD. Liver disease (chronic active hepatitis, sclerosing cholangitis) is more common. In patients with pancolitis, carcinoma of the colon occurs with an incidence of 1–2% per year after the first 10 years of disease. Cancer risk is a function of disease duration, not age at onset. The mortality rate from colon cancer is high because the usual signs (occult blood in stool, pain, and abnormal radiologic findings) are not specific and may be ignored in a patient with colitis. Routine cancer screening (colonoscopy with multiple biopsies and evaluation of specimens for metaplasia and aneuploidy) is recommended in pediatric patients after 10 years of pancolitis. Dysplasia that persists in the absence of inflammation is an indication for colectomy, as is aneuploidy in multiple biopsy specimens.

Treatment

A. Medical Treatment

Medical treatment of CD and UC is similar and includes anti-inflammatory, antidiarrheal, and antibiotic medication. No medical therapy is uniformly effective in all patients.

1. Diet—The main priority in patients with inflammatory bowel disease is ensuring adequate caloric intake. Restrictive or bland diets are counterproductive because they usually result in poor intake. A high-protein, high-carbohydrate diet with normal amounts of fat is recommended. A diet with decreased fiber may prevent symptoms during active colitis or partial intestinal obstruction; however, increased fiber may benefit mucosal health via bacterial production of fatty acids when disease is inactive. Lactose is poorly tolerated when disease is active. Supplemental calories in the form of liquid diets are well tolerated and promote catch-up growth. Enteral administration of low-residue or elemental liquid diets is widely used outside of the United States to induce remission in patients with CD. It is less effective in UC. Total parenteral nutrition for periods of 4–6 weeks may induce remission and promote linear growth and sexual development.

2. Nonabsorbable 5-aminosalicylates (5-ASA)—Multiple preparations of 5-ASA derivatives are available and are used
to induce remission in mild CD and UC. 5-ASA derivatives are also used for maintenance therapy in patients in remis-
son. Sulfasalazine, a common form of 5-ASA, is not absorbed systemically. Intact drug is hydrolyzed by colon flora into
sulfapyridine and 5-aminosalicylate. The sulfonamide moiety is probably inactive but is responsible for the allergic side
effects of the drug. The salicylate moiety has local anti-
flammatory activity. Side effects include skin rash, nausea,
headache, and abdominal pain. Rarely, serum sickness,
hemolytic anemia, aplastic anemia, and pancreatitis occur.
Response to therapy may be slow. Sulfasalazine inhibits folic
acid absorption, and supplemental folic acid is required. The
recommended dosage is 2–3 g/d in three divided doses for
children older than 10 years or 50 mg/kg/d for younger
children. Half of this dosage is used as a maintenance medi-
cation for well-controlled UC. Salicylate polymers for oral
and rectal use (olsalazine, mesalamine) are available. A vari-
y of pH-sensitive tablet coatings and microencapsulation
allow release of these products at specific locations in the GI
tract, thereby improving efficacy. These drugs are no more
effective than sulfasalazine but are used in sulfonamide-
sensitive patients and have fewer side effects.

3. Corticosteroids—Patients with moderate to severe CD
and UC require corticosteroids. Methylprednisolone (2 mg/
kg/d, maximum 60 mg/d) may be given intravenously when
disease is severe. For moderate disease, prednisone (1–2 mg/
kg/d orally in one to two divided doses) is given for 6–8
weeks followed by gradual tapering. Alternate-day steroids
produce fewer side effects as the dosage of drug is tapered.
Chronic use of corticosteroids does not prevent relapse.
Prednisone is usually given with a 5-ASA derivative. The
patient’s varicella immunity should be confirmed by history
or antibody screen and parents counseled as to risks and
therapy after varicella exposure. Hydrocortisone enemas or
rectal foam can be used to treat tenesmus or ulcerative
proctitis. Budesonide, which has “one pass metabolism” in
the liver, is available in oral and rectal preparations. These
preparations are most useful in rectal disease (enemas and
suppositories) and right-sided colon disease (oral), and in
appropriate doses have fewer corticoid side effects. Calcium
and vitamin D supplementation should be considered while
patients are being treated with corticosteroids.

4. Azathioprine and 6-mercaptopurine—Azathioprine
(Imuran), 2–3 mg/kg/d orally, or 6-mercaptopurine (1–2
mg/kg) provides effective maintenance therapy for moderate
to severe CD. These medications are used for frequently
relapsing disease or when high-dose corticosteroids are nec-
ISSITY reactions, opportunistic infections, and lymphoprolif-
erative disorders. Infliximab is also effective in severe colitis
and in steroid-dependent colitis.

7. Other Agents—Cyclosporine can be used in severe, ster-
oid-resistant UC. Because it has significant side effects and
is followed by rapid relapse after discontinuation, cyclo-
sporine is usually used to “buy time” and improve symp-
toms of severe colitis in patients prior to surgery. Oral or
subcutaneous methotrexate has been used to treat severe,
refractory CD. Liver toxicity is a risk with prolonged use.
Thalidomide has been used, especially in patients with oral
and vaginal ulcers secondary to CD. Its mechanism of action
may include prevention of TNF secretion or antiangiogenic
activity. This medication must be used under strict supervi-
sion in postpubescent female patients because of the risk of
teratogenesis.

B. Surgical Treatment

1. Crohn disease—CD is not cured by surgery. Surgery is
typically recommended for complications such as obstruc-
tion, perforation, abscess, stricture, fistula, and sometimes
for intractable symptoms, growth retardation, and pubertal
delay. Up to 50% of patients with CD eventually require a
surgical procedure. There is a high relapse rate after surgery,
typically at the site of anastomosis within 2 years. Recurrence
rate may be less in patients with disease limited to the colon.
Surgery to correct growth retardation must be performed
before the completion of puberty.

2. Ulcerative colitis—Surgery is curative and is recom-
II and unrelenting pain and diarrhea, growth failure,
high-grade mucosal dysplasia, or malignant tumors. Several
surgical approaches (ileoanostomy, Koch-type contin-
ext procedures. Infliximab is also effective in severe colitis
and in steroid-dependent colitis.

6. Biologic therapies—Infliximab, a chimeric monoclonal
antibody against tumor necrosis factor-β (TNFβ), is used for
moderate to severe CD, especially in patients with resistant
perianal and fistulizing disease unresponsive to milder ther-
apy. Most patients require repeated intravenous infusion at
4–12-week intervals to remain in remission. Anaphylactic
reactions have been reported. The concomitant use of azas-
ithioprine decreases the incidence of severe allergic reactions
and may help maintain responsiveness to therapy. Side
effects include flushing, rash, dyspnea, delayed hypersensi-
tivity reactions, opportunistic infections, and lymphoprolif-
erative disorders. Infliximab is also effective in severe colitis
and in steroid-dependent colitis.

5. Antibiotics—Metronidazole has been used to treat peri-
anal CD. It may also be effective in treating CD of the colon.
The dosage of metronidazole is 15–30 mg/kg/d in three
divided doses. Peripheral neuropathy may occur with pro-
longed use. Ciprofloxacin has similar therapeutic effect and
is occasionally used in combination with metronidazole.

4. Azathioprine and 6-mercaptopurine—Azathioprine
(Imuran), 2–3 mg/kg/d orally, or 6-mercaptopurine (1–2
mg/kg) provides effective maintenance therapy for moderate
to severe CD. These medications are used for frequently
relapsing disease or when high-dose corticosteroids are nec-
1. Crohn disease—CD is not cured by surgery. Surgery is

and in steroid-dependent colitis.

5. Antibiotics—Metronidazole has been used to treat peri-
anal CD. It may also be effective in treating CD of the colon.
The dosage of metronidazole is 15–30 mg/kg/d in three
divided doses. Peripheral neuropathy may occur with pro-
longed use. Ciprofloxacin has similar therapeutic effect and
is occasionally used in combination with metronidazole.

4. Azathioprine and 6-mercaptopurine—Azathioprine
(Imuran), 2–3 mg/kg/d orally, or 6-mercaptopurine (1–2
mg/kg) provides effective maintenance therapy for moderate
to severe CD. These medications are used for frequently
relapsing disease or when high-dose corticosteroids are nec-

style after colectomy. Liver disease associated with UC (sclerosing cholangitis) is not improved by colectomy.

Liver Disorders

Prolonged Neonatal Cholestasis

The main clinical features of disorders causing prolonged neonatal cholestasis are (1) jaundice with elevated serum conjugated (or direct) bilirubin fraction (> 2 mg/dL or > 20% of total bilirubin), (2) variably acholic stools, (3) dark urine, and (4) hepatomegaly.

Prolonged neonatal cholestasis (conditions with decreased bile flow) has intrahepatic and extrahepatic causes. Specific clinical clues (Table 21–1) distinguish these two major categories of jaundice in 85% of cases. Histologic examination of tissue obtained by percutaneous liver biopsy increases the accuracy of differentiation to 95% (Table 21–2).

Intrahepatic Cholestasis

Essentials of Diagnosis & Typical Features

- Elevated total and conjugated bilirubin.
- Hepatomegaly and dark urine.
- Patency of extrahepatic biliary tree.

General Considerations

Intrahepatic cholestasis is characterized by hepatocyte dysfunction and patency of the extrahepatic biliary system. A specific cause can be identified in about 50% of cases. Patency of the extrahepatic biliary tract is suggested by pigmented stools and lack of bile duct proliferation on liver biopsy. It can be confirmed least invasively by hepatobiliary scintigraphy using technetium-99m (\(^{99m}\)Tc)-diethyliminoacetic acid (diethyl-IDA [DIDA]). Radioactivity in the bowel within 4–24 hours is evidence of bile duct patency. Finding bilirubin in duodenal aspirates also confirms patency. Patency can also be determined by cholangiography carried out infraoperatively, percutaneously by transhepatic cholecystography, or endoscopic retrograde cholangiopancreatography (ERCP) using a pediatric-size side-viewing endoscope. Magnetic resonance cholangiopancreatography in infants is of limited use and highly dependent on the operator and equipment.

1. Perinatal or Neonatal Hepatitis Resulting from Infection

This diagnosis is considered in infants with jaundice, hepatomegaly, vomiting, lethargy, fever, and petechiae. It is important to identify perinatally acquired viral, bacterial, or protozoal infections (Table 21–3). Infection may occur transplacentally, by ascent through the cervix into amniotic fluid, from swallowed contaminated fluids (maternal blood, urine) during delivery, from blood transfusions administered in the early neonatal period, or from breast milk or environmental exposure. Infectious agents associated with neonatal intrahepatic cholestasis include herpes simplex virus, varicella virus, enteroviruses (coxackievirus and echovirus), cytomegalovirus (CMV), rubella virus, adenovirus, parvovirus, human herpesvirus type 6 (HHV-6), hepatitis B virus (HBV), human immunodeficiency virus (HIV), Treponema pallidum, and Toxoplasma gondii. Although hepatitis C may be transmitted vertically, it rarely causes neonatal cholestasis. The degree of liver cell injury caused by these agents is variable, ranging from massive hepatic necrosis (herpes simplex, enteroviruses) to focal necrosis and mild inflammation (CMV, HBV). Serum bilirubin, bile acids, alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase are elevated. The infant is jaundiced, may have petechiae or rash, and generally appears ill.
Clinical Findings
A. Symptoms and Signs

Clinical symptoms usually appear in the first 2 weeks of life, but may appear as late as age 2–3 months. Jaundice may be noted as early as the first 24 hours of life. Poor oral intake, poor sucking reflex, lethargy, and vomiting are frequent. Stools may be normal to pale in color but are seldom acholic. Dark urine stains the diaper. Hepatomegaly is present, and the liver has a uniform firm consistency. Splenomegaly is variably present. Macular, papular, vesicular, or petechial rashes may occur. In less severe cases, failure to thrive may be the major complaint. Unusual presentations include neonatal liver failure, hypoproteinemia, anasarca (nonhemolytic hydrops), and hemorrhagic disease of the newborn.

B. Diagnostic Studies

Neutropenia, thrombocytopenia, and signs of mild hemolysis are common. Mixed hyperbilirubinemia, elevated aminotransferases with near-normal alkaline phosphatase, prolongation of clotting studies, mild acidosis, and elevated cord serum IgM suggest congenital infection. Nasopharyngeal washings, urine, stool, serum, and cerebrospinal fluid (CSF) should be cultured for virus and tested for pathogen-specific nucleic acid. Specific IgM antibody may be useful, as are long-bone radiographs to determine the presence of “celery stalking” in the metaphyseal regions of the humeri, femurs, and tibias. When indicated, computed tomography (CT) and magnetic resonance imaging (MRI) scans can identify intracranial calcifications (especially with CMV and toxoplasmosis). Hepatobiliary scintigraphy shows decreased hepatic clearance of the circulating isotope with excretion into the gut. Careful ophthalmologic examination may be useful for diagnosis of herpes simplex virus, CMV, toxoplasmosis, and rubella.

A percutaneous liver biopsy is useful in distinguishing intrahepatic from extrahepatic cholestasis, but may not identify a specific infectious agent (see Table 21–2). However, typical inclusions of CMV in hepatocytes or bile duct epithelial cells, the presence of intranuclear acidophilic inclusions of herpes simplex, or positive immunohistochemical stains for several viruses can be diagnostic. Variable degrees of lobular disarray characterized by focal necrosis, multinucleated giant-cell transformation, and ballooned pale hepatocytes with loss of cordlike arrangement of liver cells are usual. Intrahepatic and canalicular cholestasis may be prominent. Portal changes are not striking, but modest neoductular proliferation and mild fibrosis may occur. Viral cultures or polymerase chain reaction (PCR) testing of biopsy material may be helpful.

Differential Diagnosis

Great care must be taken to distinguish infectious causes of intrahepatic cholestasis from genetic or metabolic disorders because the clinical presentations are similar. Galactosemia, congenital fructose intolerance, and tyrosinemia must be investigated promptly, because specific dietary therapy is available. These infants may also have concomitant bacteremia. α1-Antitrypsin deficiency, cystic fibrosis, bile acid synthesis defects, mitochondrial respiratory chain disorders, and neonatal iron storage disease must also be considered. Specific physical features may be helpful when considering Alagille or Zellweger syndrome. Idiopathic neonatal hepatitis may be indistinguishable from infectious causes.

Patients with intrahepatic cholestasis frequently appear ill, whereas infants with extrahepatic cholestasis do not appear ill, have stools that are usually completely acholic, and have an enlarged, firm liver. Histologic findings are described in Table 21–2.

Treatment

Most forms of viral neonatal hepatitis are treated symptomatically. However, infections with herpes simplex virus, varicella, CMV, parvovirus, adenovirus, and toxoplasmosis have specific treatments. Fluids and adequate calories are encouraged. Intravenous dextrose is needed if feedings are not well tolerated. The consequences of cholestasis are treated as indicated (Table 21–4). Vitamin K orally or by injection and vitamins D and E orally should be provided. Choleretics (ursodeoxycholic acid [UDCA] or cholestyramine) are used if cholestasis persists. Corticosteroids are contraindicated. Penicillin for suspected syphilis, specific antiviral therapy, or antibiotics for bacterial hepatitis, need to be administered promptly.

Prognosis

Multiple organ involvement is commonly associated with neonatal infectious hepatitis and has a poor outcome. Death from hepatic or cardiac failure, intractable acidosis, or intracranial hemorrhage may occur, especially in herpesvirus or enterovirus infection, and occasionally in CMV or rubella infection. HBV rarely causes fulminant neonatal hepatitis; most infected infants become asymptomatic carriers of hepatitis B. Persistent liver disease results in mild chronic hepatitis, portal fibrosis, or cirrhosis. The liver in most infants who recover from congenital viral infection is left without fibrosis. Chronic cholestasis, although rare following infections, may lead to dental enamel hypoplasia, failure to thrive, biliary rickets, severe pruritus, and xanthoma.

2. Specific Infectious Agents

A. Neonatal Hepatitis B Virus Disease

Infection with HBV may occur at any time during perinatal life, but the risk is higher when acute maternal disease occurs during the last trimester of pregnancy. However, most cases of neonatal disease are acquired from mothers who are asymptomatic carriers of HBV. Although HBV has been found in most body fluids, including breast milk, neonatal transmission occurs occasionally transplacentally and primarily from exposure to maternal blood at delivery. In chronic hepatitis B surface antigen (HBsAg)–carrier mothers, fetal and infant acquisition risk is greatest if the mother (1) is also hepatitis B “e” antigen (HBeAg)–positive and hepatitis B “e” antibody (HBeAb)–negative, (2) has detectable levels of serum-specific hepatitis B DNA polymerase, (3) has high serum levels of hepatitis B core antibody (HBcAb), or (4) has high blood levels of HBV DNA. These findings are markers for circulating infectious virus; however, hepatitis B can be transmitted even if HBsAg is the only marker present.

Neonatal liver disease resulting from HBV is extremely variable. The infant has a 70–90% chance of acquiring HBV at birth from an HBsAg-positive mother if the infant does not receive prophylaxis. Most infected infants become prolonged asymptomatic “carriers” of HBV. Fulminant hepatic necrosis
has rarely been reported. In such cases, progressive jaundice, stupor, shrinking liver size, and coagulation abnormalities dominate the clinical picture. Respiratory, circulatory, and renal failure usually follow. Histologically, the liver shows massive hepatocyte necrosis, collapse of the reticulum framework, minimal inflammation, and occasional pseudoacinar structures. Survival without liver transplantation is rare, but is associated with reasonable repair of liver architecture.

*α- tocopherol polyethylene glycol-1000 succinate.
In less severe cases, focal hepatocyte necrosis occurs with a mild portal inflammatory response. Cholestasis is intracellular and canalicular. Chronic hepatitis may persist for many years, with serologic evidence of persisting antigensemia (HBsAg) and mildly elevated serum aminotransferases. Chronic hepatitis may rarely progress to cirrhosis within 1–2 years. Most infected infants have only mild evidence, if any, of liver injury.

To prevent perinatal transmission, all infants of mothers who are HBsAg-positive (regardless of HBeAg status) should receive hepatitis B immunoglobulin (HBIG) and hepatitis B vaccine within the first 24 hours after birth and vaccine again at ages 1 and 6 months. (See Chapter 9.) This prevents HBV infection in 85–95% of infants. HBIG can provide some protection when given as late as 72 hours after birth. If not given at birth it can be administered as late as 7 days postpartum as long as the infant has received the vaccine. Universal HBV immunization at birth, with two follow-up doses, is recommended for all infants.

B. Neonatal Bacterial Hepatitis

Most bacterial liver infections in newborns are acquired by transplacental invasion from amnionitis with ascending spread from maternal vaginal or cervical infection. Onset is abrupt, usually within 48–72 hours after delivery, with signs of sepsis and often shock. Jaundice appears early and is of the mixed type. The liver enlarges rapidly, and the histologic picture is that of diffuse hepatitis with or without microabscesses. The most common organisms involved are *Escherichia coli*, *Listeria monocytogenes*, and group B streptococci. Isolated neonatal liver abscess caused by *E. coli* or *Staphylococcus aureus* is associated with omphalitis or umbilical vein catheterization.

Bacterial hepatitis and neonatal liver abscesses require specific antibiotics in large doses and, rarely, surgical or radiologic interventional drainage. Deaths are common, but survivors show no long-term consequences of liver disease.

C. Neonatal Jaundice with Urinary Tract Infection

Jaundice in affected infants—usually males—typically appears between the second and fourth weeks of life. This disorder causes lethargy, fever, poor appetite, jaundice, and hepatomegaly. Except for mixed hyperbilirubinemia, other liver function tests (LFTs) are mildly abnormal. Leukocytosis is present, and infection is confirmed by urine culture. The mechanism for the liver impairment is the inhibitory action on bile secretion produced by bacterial products (endotoxins) and inflammatory cytokines.

Treatment of the infection leads to prompt resolution of the cholestasis without hepatic sequela. Metabolic liver diseases, such as galactosemia and tyrosinemia, may present with gram-negative bacterial urinary tract infection and should be excluded.

3. Intrahepatic Cholestasis Resulting from Inborn Errors of Metabolism, Familial, & “Toxic” Causes

These cholestatic syndromes caused by specific enzyme deficiencies, other genetic disorders, or certain precipitants associated with neonatal liver disease feature intrahepatic cholestasis (ie, jaundice, hepatomegaly, and normal to completely acholic stools). Some of the specific clinical conditions have characteristic clinical signs.

A. Enzyme Deficiencies and Other Inherited Disorders

Early specific diagnosis is important because dietary or pharmacologic treatment may be available (Table 21–5). Reversal of liver disease and clinical symptoms is prompt and permanent in several disorders as long as the diet is maintained. As with other genetic disorders, parents of the affected infant should be offered genetic counseling. For some disorders, prenatal genetic diagnosis is available.

Cholestasis caused by metabolic diseases such as galactosemia, fructose intolerance, and tyrosinemia may be accompanied by vomiting, lethargy, poor feeding, hypoglycemia, and irritability. Hepatomegaly is a constant finding.

The infants often appear septic; gram-negative bacteria can be cultured from blood in 25–50% of cases. Liver function studies reveal mixed hyperbilirubinemia, elevated alkaline phosphatase and γ-glutamyl transpeptidase (GGT) values, and variable elevation of the aminotransferases. Stools are seldom persistently acholic.

Choleretics (UDCA), introduction of enteral feedings as soon as possible, and nutritional support are the mainstays of treatment until the cholestasis resolves (see Table 21–4). In some cases, this resolution may take 3–6 months. As long as no severe intestinal problem is present (eg, short gut syndrome), complete resolution of the hepatic abnormalities is the rule. But portal fibrosis with periportal scarring is occasionally found on follow-up biopsy.

2. Prolonged parenteral nutrition—Cholestasis may develop after 1–2 weeks in premature newborns receiving parenteral nutrition. Even full-term infants with significant intestinal disease, resections, or dysmotility may develop parenteral nutrition–related cholestasis. Contributing factors may include toxicity of intravenous amino acids, diminished stimulation of bile flow from prolonged absence of feedings, small intestinal bacterial overgrowth with translocation of intestinal bacteria and their cell wall products, missing nutrients or antioxidants, photooxidation of amino acids, infusion of lipid hydroperoxides or lipid sterols, and the “physiologic cholestatic” propensity of the premature infant. Histology of the liver may resemble that of extrahepatic biliary obstruction. Early introduction of feedings has reduced the frequency of this disorder. The prognosis is generally good. Occasional cases of cirrhosis, liver failure, and hepatoma may develop, particularly in infants with intestinal resections or malformations that require prolonged parenteral nutrition. A recent study suggests that oral erythromycin as a prokinetic agent may reduce the incidence of cholestasis in very low birth infants.

3. Insipissated bile syndrome—This syndrome is the result of accumulation of bile in canaliculi and in the small- and medium-sized bile ducts in hemolytic disease of the newborn (Rh, ABO) and in some infants receiving parenteral nutrition. The same mechanisms may cause intrinsic obstruction of the common bile duct. An ischemia-reperfusion injury may also contribute to cholestasis in Rh incompatibility. In extreme hemolysis, the cholestasis may be seemingly complete, with acholic stools. Levels of bilirubin, primarily conjugated, may reach 40 mg/dL. If inspissation of bile occurs within the extrahepatic biliary tree, differentiation from biliary atresia may be difficult. A trial of choleretics is indicated. Once stools show a return to normal color or 99mTc-DIDA scanning shows biliary excretion into the duodenum, patency of the extrahepatic biliary tree is assured. Although most cases improve slowly over 2–6 months, persistence of complete cholestasis for more than 1–2 weeks requires further studies (ultrasonography, DIDA scanning, liver biopsy) with possible cholangiographic or MRI of the extrahepatic biliary tree. Irrigation of the common bile duct is sometimes necessary to dislodge the obstructing inspissated biliary material.

4. Idiopathic Neonatal Hepatitis (Giant-Cell Hepatitis)

This type of cholestatic jaundice of unknown cause presents with features of cholestasis and a typical liver biopsy appearance; it accounts for 25–40% of cases of neonatal intrahepatic cholestasis. The degree of cholestasis is variable, and the disorder may be indistinguishable from extrahepatic causes in 10% of cases. Viral infections, α1-antitrypsin deficiency, Alagille syndrome, Niemann-Pick type C disease (NPC), progressive familial intrahepatic cholestasis (PFIC), and bile acid synthesis defects may present in a similar clinical and histologic manner. In idiopathic neonatal hepatitis, PFIC types 1 and 2, and disease due to bile acid synthesis defects the GGT levels are normal or low. Electron microscopy of the liver biopsy (and genotyping) may help distinguish NPC and PFIC.

Intrauterine growth retardation, prematurity, poor feeding, emesis, poor growth, and partially or intermittently acholic stools are characteristic of intrahepatic cholestasis. Patients with neonatal lupus erythematosus may present with giant-cell hepatitis; however, thrombocytopenia, skin rash, or congenital heart block is usually also present.

In cases of suspected idiopathic neonatal hepatitis (diagnosed in the absence of infectious, metabolic, and toxic causes), patency of the biliary tree should be verified to exclude extrahepatic surgical disorders. DIDA scanning and ultrasonography may be helpful in this regard if stools are acholic. Some clinicians have used the enteral string test during DIDA scanning to confirm bile duct patency. Liver biopsy findings are usually diagnostic after age 6–8 weeks (see Table 21–2), but may be misleading before age 6 weeks. Failure to detect patency of the biliary tree, nondiagnostic liver biopsy findings, or persisting complete cholestasis (acholic stools) are indications for minilaparotomy and intraoperative cholangiography performed by an experienced surgeon, ERCP, percutaneous cholecystography, or magnetic resonance cholangiopancreatography (MRCP). Occasionally, a small but patent (hypoplatic) extrahepatic biliary tree is demonstrated (as in Alagille syndrome); it is probably the result, rather than the cause, of diminished bile flow. Surgical reconstruction of hypoplatic biliary trees should not be attempted.

Once a patent extrahepatic tree is confirmed, therapy should include choleretics, a special formula with medium-chain triglycerides (eg, Pregestimil, Alimentum), and supplemental fat-soluble vitamins in water-soluble form (see Table 21–4). This therapy is continued as long as significant cholestasis remains (conjugated bilirubin > 1 mg/dL). Fat-soluble vitamin serum levels should be monitored while supplements are given and at least once after their discontinuation.
Eighty percent of patients recover without significant hepatic fibrosis. However, in 20% of cases the patient has PFIC and is likely to progress to cirrhosis. In general, failure to resolve the cholestatic picture by age 6–12 months is associated with progressive liver disease and evolving cirrhosis. This may occur with either normal or diminished numbers of interlobular bile ducts (paucity of interlobular ducts). Liver transplantation has been successful when signs of hepatic decompensation are noted (rising bilirubin, coagulopathy, intractable ascites).

5. Paucity of Interlobular Bile Ducts

Forms of intrahepatic cholestasis caused by decreased numbers of interlobular bile ducts (< 0.5 bile ducts per portal tract) may be classified according to whether they are associated with other malformations. Alagille syndrome (syndromic paucity or arteriohepatic dysplasia) is caused by mutations in the gene JAGGED1, located on chromosome 20p, which codes for a ligand of the notch receptor, or more rarely in the gene NOTCH2. Alagille syndrome is sometimes recognized by identification of the characteristic facies, which becomes more obvious with age. The forehead is prominent, as is the nasal bridge. The eyes are set deep and sometimes widely apart (hypertelorism). The chin is small and slightly pointed and projects forward. The ears are prominent. The stoo color varies with the severity of cholestasis. Pruritus begins by age 3–6 months. Firm, smooth hepatomegaly may be present. Cardiac murmurs are present in 95% of patients, and butterfly vertebrae (incomplete fusion of the vertebral body or anterior arch) are present in 50%. Xanthomas develop later in the disease as hypercholesterolemia becomes a problem. Occasionally, early cholestasis is mild and not recognized or the patient presents with complex congenital heart disease (eg, tetralogy of Fallot).

Conjugated hyperbilirubinemia may be mild to severe (2–15 mg/dL). Serum alkaline phosphatase, GGT, and cholesterol are markedly elevated, especially early in life. Serum bile acids are always elevated. Aminotransferases are mildly increased, but clotting factors and other liver proteins are usually normal.

The cardiovascular abnormalities include peripheral pulmonary artery, branch pulmonary artery, or pulmonary valvular stenoses (most common), atrial septal defect, coarctation of the aorta, and tetralogy of Fallot. Up to 10–15% of patients have intracranial vascular abnormalities and may develop intracranial hemorrhage early in childhood.

Eye abnormalities (posterior embryotoxon in 90%) and renal abnormalities (dysplastic kidneys, renal tubular ectasia, single kidney, hematuria) can also be present. Growth retardation with normal to increased levels of growth hormone (growth hormone resistance) is common. A variable proportion of patients may have pancreatic insufficiency that may contribute to the fat malabsorption. Although variable, the intelligence quotient is frequently low. Hypogonadism with micropenis may be present. A weak, high-pitched voice may develop. Neurologic disorders resulting from vitamin E deficiency (areflexia, ataxia, ophthalmoplegia) eventually develop in many unsupplemented children and may be profound.

In the nonsyndromic form, paucity of interlobular bile ducts occurs in the absence of the extrahepatic malformations. Paucity of interlobular bile ducts may also occur in α1-antitrypsin deficiency, Zellweger syndrome, in association with lymphedema (Aagenaes syndrome), PFIC, cystic fibrosis, CMV or rubella infection, and inborn errors of bile acid metabolism.

High doses (250 mg/kg/d) of cholestyramine may control pruritus, lower cholesterol, and clear xanthomas. UDCA (15–25 mg/kg/d) appears to be more effective and causes fewer side effects than cholestyramine. Nutritional therapy to prevent wasting and deficiencies of fat-soluble vitamins is of particular importance because of the severity of cholestasis (see Table 21–4).

Prognosis is more favorable in the syndromic than in the nonsyndromic varieties. In the former, only 30–40% of patients have severe complications of disease, whereas over 70% of patients with nonsyndromic varieties progress to cirrhosis. Many of this latter group may have PFIC. In Alagille syndrome, cholestasis may improve by age 2–4 years, with minimal residual hepatic fibrosis. Survival into adulthood despite raised serum bile acids, aminotransferases, and alkaline phosphatase occurs in about 50% of cases. Several patients have developed hepatocellular carcinoma. Hypogonadism has been noted; however, fertility is not obviously affected in most cases. Cardiovascular anomalies may shorten life expectancy. Some patients have persistent, severe cholestasis, rendering their quality of life poor. Recurrent bone fractures may result from metabolic bone disease. Liver transplantation has been successfully performed under these circumstances. Intracranial hemorrhage may occur in up to 10–12% of affected children.

PROGRESSIVE FAMILIAL INTRAHEPATIC CHOLESTASIS (BYLER DISEASE)

PFIC is a group of disorders presenting as pruritus, diarrhea, jaundice, and failure to thrive in the first 6–12 months of life. PFIC type I (Byler disease), caused by mutations in the \( FIC1 \) gene, is associated with low to normal serum levels of GGT and cholesterol and elevated levels of bilirubin, aminotransferases, and bile acids. Diarrhea and pruritus are common. Liver biopsy demonstrates cellular cholestasis, sometimes with a paucity of interlobular bile ducts and centrolobular fibrosis that progresses to cirrhosis. Electron microscopy shows diagnostic granular “Byler bile” in canaliculi.

Treatment includes administration of UDCA, partial biliary diversion if the condition is unresponsive to UDCA, and liver transplantation. With partial biliary diversion or ileal exclusion surgery, many patients show improved growth and liver histology, reduction in symptoms and, thus, avoidance of liver transplantation. PFIC type II is caused by mutations in the bile salt export pump (\( BSEP \)) gene, which codes for an adenosine triphosphate–dependent canalicular bile salt transport protein. These patients are clinically and biochemically similar to PFIC type I patients and have similar liver histology except for more “giant cells” and treatment options. There is an increased incidence of hepatocellular carcinoma in these patients.

PFIC type III is caused by mutations in the multiple drug resistance protein type 3 (\( MDR3 \)) gene, which encodes a canalicular protein that pumps phospholipid into bile. Serum GGT and bile acid levels are elevated, bile duct proliferation and portal tract fibrosis are seen in liver biopsies, and bile phospholipid levels are low. Treatment is similar to that for other forms of PFIC except for partial biliary diversion. Bile acid synthesis defects are clinically similar to PFIC I and PFIC II, with low serum levels of GGT and cholesterol; however, the serum level of total bile acids is inappropriately normal or low and urine bile acid analysis may identify a synthesis defect. Treatment is with oral cholic acid and UDCA.

EXTRAHEPATIC NEONATAL CHOLESTASIS

Extrahepatic neonatal cholestasis is characterized by complete and persistent cholestasis (acholic stools) in the first 3 months of life; lack of patency of the extrahepatic biliary tree proved by intraoperative, percutaneous, or endoscopic cholangiography; firm to hard hepatomegaly; and typical features on histologic examination of liver biopsy tissue (see Table 21–2). Causes include biliary atresia, choledochal cyst, spontaneous perforation of the extrahepatic ducts, and intrinsic or extrinsic obstruction of the common duct.

1. Biliary Atresia

   ◀️ General Considerations

Biliary atresia is the progressive fibroinflammatory obliteration of the lumen of all, or part of, the extrahepatic biliary tree presenting within the first 3 months of life. In Americans of European origin, biliary atresia occurs in 1:10,000–1:18,000 births, and the incidence in both sexes is equal. In Asian Americans the incidence is higher and the disorder is more common in girls. The abnormality found most commonly is complete atresia of all extrahepatic biliary structures. There appear to be at least two types of biliary atresia: the perinatal form (80% of cases), in which a perinatal insult is believed to initiate inflammatory obstruction and fibrosis of the biliary tree, and the fetal-embryonic form (20% of cases), in which the extrahepatic biliary system did not develop normally. In the perinatal form, meconium and first-passed stools are usually normal in color, suggesting early patency of the ducts. Evidence obtained from surgically removed remnants of the extrahepatic biliary tree suggests an inflammatory or sclerosing cholangiopathy. Although an infectious cause seems reasonable, no agent has been consistently found in such cases. A role for rotevirus type 3 and rotavirus group C has been suggested. In the fetal-embryonic type, the bile duct presumably developed abnormally and is associated with other nonhepatic congenital anomalies. The association of biliary atresia with the polysplenia syndrome (heterotaxia, preduodenal portal vein, interruption of the inferior vena cava, polysplenia, and midline liver) and asplenia syndrome supports an embryonic origin of biliary atresia in these cases.

   ◀️ Clinical Findings

A. Symptoms and Signs

Jaundice may be noted in the newborn period and persists beyond age 2–3 weeks. The urine stains the diaper; and the stools are often pale yellow, buff-colored, gray, or acholic. Seepage of bilirubin products across the intestinal mucosa may give some yellow coloration to the stools. Hepatomegaly is common, and the liver may feel firm to hard; splenomegaly develops later. Pruritus, digital clubbing, xanthomas, and a rachitic rosary may be noted in older patients. By age 2–6 months, the growth curves reveal poor weight gain. Late in the course, ascites, failure to thrive, bone fractures and bleeding complications occur.
B. Laboratory Findings and Imaging

No single laboratory test will consistently differentiate biliary atresia from other causes of complete obstructive jaundice. A study of hepatic 2,6-dimethyliminodiacetic acid (HIDA) excretion performed early in the course of disease may help to distinguish intrahepatic from extrahepatic causes of cholestasis, although there is considerable overlap. A HIDA scan showing lack of intestinal excretion is always present in biliary atresia also but may be seen with intrahepatic cholestasis. MRCP may be of value as an imaging study to define biliary atresia. Although biliary atresia is suggested by persistent elevation of serum GGT or alkaline phosphatase levels, high cholesterol levels, and prolonged prothrombin times, these findings have also been reported in severe neonatal hepatitis, α1-antitrypsin deficiency, and bile duct paucity. Furthermore, these tests will not differentiate the location of the obstruction within the extrahepatic system. Generally, the aminotransferases are elevated only modestly in biliary atresia. Serum proteins and blood clotting factors are not affected early in the disease. Routine chest radiograph may reveal abnormalities suggestive of polysplenia syndrome. Ultrasonography of the biliary system should be performed to exclude the presence of choledochal cyst and intra-abdominal anomalies. Liver biopsy specimens can differentiate intrahepatic cholestasis from biliary atresia in over 90% of cases (see Table 21–2).

Differential Diagnosis

The major diagnostic dilemma is distinguishing between this entity and neonatal hepatitis, bile duct paucity, metabolic liver disease (particularly α1-antitrypsin deficiency), choledochal cyst, or intrinsic bile duct obstruction (stones, bile plugs). Although spontaneous perforation of extrahepatic bile ducts leads to jaundice and acholic stools, the infants are usually quite ill with chemical peritonitis from biliary ascites, bile acid (HIDA) excretion performed early in the course of jaundice. A study of hepatic 2,6-dimethyliminodiacetic acid (HIDA) excretion performed early in the course of disease may help to distinguish intrahepatic from extrahepatic causes of cholestasis, although there is considerable overlap. A HIDA scan showing lack of intestinal excretion is always present in biliary atresia also but may be seen with intrahepatic cholestasis. MRCP may be of value as an imaging study to define biliary atresia. Although biliary atresia is suggested by persistent elevation of serum GGT or alkaline phosphatase levels, high cholesterol levels, and prolonged prothrombin times, these findings have also been reported in severe neonatal hepatitis, α1-antitrypsin deficiency, and bile duct paucity. Furthermore, these tests will not differentiate the location of the obstruction within the extrahepatic system. Generally, the aminotransferases are elevated only modestly in biliary atresia. Serum proteins and blood clotting factors are not affected early in the disease. Routine chest radiograph may reveal abnormalities suggestive of polysplenia syndrome. Ultrasonography of the biliary system should be performed to exclude the presence of choledochal cyst and intra-abdominal anomalies. Liver biopsy specimens can differentiate intrahepatic cholestasis from biliary atresia in over 90% of cases (see Table 21–2).

Treatment

In the absence of surgical correction or transplantation, biliary cirrhosis, hepatic failure, and death occur, almost always by age 18–24 months.

Except for the occasional example of correctable biliary atresia, in which choledochojejunostomy is feasible, the standard procedure is hepatopancreatoenterostomy (Kasai procedure). Occasionally, portocholecystostomy (gallbladder Kasai procedure) may be performed if the gallbladder is present and the passage from it to the duodenum is patent. These procedures are best done in specialized centers where experienced surgical, pediatric, and nursing personnel are available. Surgery should be performed as early as possible (ideally before 45–60 days of life); the Kasai procedure should generally not be undertaken in infants older than age 4 months, because the likelihood of bile drainage at this age is very low. Orthotopic liver transplantation is now indicated for patients who do not undergo the Kasai procedure, who fail to drain bile after the Kasai procedure, or who progress to end-stage biliary cirrhosis despite surgical treatment. The 3–5-year survival rate following liver transplantation for biliary atresia is 80–90%.

Whether or not the Kasai procedure is performed, supportive medical treatment measures consist of vitamin and caloric support (vitamins A, D, K, and E and formulas containing medium-chain triglycerides [Pregestimil or Alimentum]) (see Table 21–4). Suspected bacterial infections (eg, ascending cholangitis) should be treated promptly with broad-spectrum antibiotics, and any bleeding tendency should be corrected with intramuscular vitamin K. Ascites can be managed initially with reduced sodium intake and spironolactone. Choleretics and bile acid–binding products (cholestyramine, aluminum hydroxide gel) are of little use. The value of UDCA remains to be determined. The role of postoperative corticosteroids is controversial.

Prognosis

When bile flow is sustained following portoenterostomy, the 10-year survival rate without liver transplantation is 25–35%. Death is usually caused by liver failure, sepsis, acidosis, or respiratory failure secondary to intractable ascites. Esophageal variceal hemorrhage develops in 40% of patients. Surprisingly, terminal hemorrhage is unusual. Occasional long-term survivors develop hepatopulmonary syndrome (intrapulmonary right to left shunting of blood resulting in hypoxia) or portopulmonary hypertension (pulmonary arterial hypertension in patients with portal hypertension). Liver transplantation has dramatically changed the outlook for these patients.

2. Choledochal Cyst

Choledochal cysts cause 2–5% of cases of extrahepatic neonatal cholestasis; the incidence is fourfold higher in girls and higher in patients of Asian descent. In most cases, the clinical manifestations, basic laboratory findings, and histopathologic features on liver biopsy are indistinguishable from those associated with biliary atresia. Neonatal symptomatic cysts are usually associated with atresia of the distal common duct—accounting for the diagnostic dilemma—and may simply be part of the spectrum of biliary atresia. Ultrasonography or MRI reveals the presence of a cyst. Immediate surgery is indicated once abnormalities in clotting factors have been corrected and bacterial cholangitis, if present, has been treated with intravenous antibiotics. In older children, choledochal cyst presents as recurrent episodes of right upper quadrant abdominal pain, vomiting, obstructive jaundice, or pancreatitis, or as a right abdominal mass.

Excision of the cyst and choledocho–Roux-en-Y jejunal anastomosis are recommended. In some cases, because of technical problems, only the mucosa of the cyst can be removed with jejunal anastomosis to the proximal bile duct. Anastomosis of cyst to jejunum or duodenum is not recommended.

The prognosis depends on the presence or absence of associated evidence of atresia and the appearance of the intrahepatic ducts. If atresia is found, the prognosis is similar to that described in the preceding section. If an isolated extrahepatic cyst is encountered, the outcome is generally excellent, with resolution of the jaundice and return to normal liver architecture. However, bouts of ascending cholangitis may occur, particularly if intrahepatic cysts are present or obstruction of the anastomatic site develops. The risk of biliary carcinoma developing within the cyst is about 5–15% at adulthood; therefore, cystectomy or excision of cyst mucosa should be undertaken whenever possible.

3. Spontaneous Perforation of the Extrahepatic Bile Ducts

The sudden appearance of obstructive jaundice, acholic stools, and abdominal enlargement with ascites in a sick newborn is suggestive of this condition. The liver is usually normal in size, and a yellow-green discoloration can often be discerned under the umbilicus or in the scrotum. In 24% of cases, stones or sludge obstructs the common bile duct. DIDA scan or ERCP shows leakage from the biliary tree, and ultrasonography confirms ascites or fluid around the bile duct.

Treatment is surgical. Simple drainage, without attempts at oversewing the perforation, is sufficient in primary perforations. A diversion anastomosis is constructed in cases associated with choledochal cyst or stenosis. The prognosis is generally good.

OTHER NEONATAL HYPERBILIRUBINEMIC CONDITIONS (NONCHOLESTATIC NONHEMOlyTIC)

This group of disorders is associated with hyperbilirubinemia of two types: (1) unconjugated hyperbilirubinemia, present in breast milk jaundice, Lucey-Driscoll syndrome, congenital hypothyroidism, upper intestinal obstruction, Gilbert disease, Crigler-Najjar syndrome, and drug-induced hyperbilirubinemia; and (2) conjugated noncholestatic hyperbilirubinemia, present in the Dubin-Johnson syndrome and Rotor syndrome.

1. Unconjugated Hyperbilirubinemia

A. Breast Milk Jaundice

Persistent elevation of the indirect bilirubin fraction may occur in up to 36% of breast-fed infants. Enhanced β-glucuronidase activity in breast milk is one factor that increases absorption of unconjugated bilirubin. Substances (eg, l-aspartic acid) in casein hydrolysate formulas inhibit this enzyme. The increased enterohepatic shunting of unconjugated bilirubin exceeds the normal conjugating capacity in the liver of these infants. The mutation for Gilbert syndrome predisposes to breast milk jaundice and to more prolonged jaundice. Low volumes of ingested breast milk may also contribute to jaundice in the first week of life.

Hyperbilirubinemia does not usually exceed 20 mg/dL, with most cases in the range of 10–15 mg/dL. In patients whose bilirubin levels are above 4–5 mg/dL, the jaundice is noticeable by the fifth to seventh day of breast feeding. It may accentuate the underlying physiologic jaundice—especially early, when total fluid intake may be less than optimal. Except for jaundice, the physical examination is usually normal; urine does not stain the diaper, and the stools are golden yellow.

The jaundice peaks before the third week of life and clears before age 3 months in almost all infants, even when breast feeding is continued. All infants who remain jaundiced past age 2–3 weeks should have measurements of conjugated bilirubin to exclude hepatobiliary disease.
Kernicterus has rarely been reported in association with this condition. In special situations, breast feeding may be discontinued temporarily and replaced by formula feedings for 2–3 days until serum bilirubin decreases by 2–8 mg/dL. Cow’s milk formulas inhibit the intestinal reabsorption of unconjugated bilirubin. When breast feeding is reinstituted, the serum bilirubin may increase slightly, but not to the previous level. Phototherapy is not indicated in the healthy full-term infant with this condition unless bilirubin levels meet high-risk levels as defined by the American Academy of Pediatrics.

B. Congenital Hypothyroidism

Although the differential diagnosis of indirect hyperbilirubinemia should always include congenital hypothyroidism, the diagnosis may be obvious from other clinical and physical clues or from the newborn screening results. The jaundice clears quickly with replacement thyroid hormone therapy, although the mechanism is unclear.

C. Upper Intestinal Obstruction

The association of indirect hyperbilirubinemia with high intestinal obstruction (eg, duodenal atresia, annular pancreas, pyloric stenosis) in the newborn has been observed repeatedly; the mechanism is unknown. Diminished levels of hepatic glucuronyl transferase have been found on liver biopsy in pyloric stenosis, and genetic studies suggest that this indirect hyperbilirubinemia is an early sign of Gilbert syndrome.

Treatment is that of the underlying obstructive condition (usually surgical). Jaundice disappears once adequate nutrition is achieved.

D. Gilbert Syndrome

Gilbert syndrome is a common form (3–7% of the population) of familial hyperbilirubinemia associated with a partial reduction of hepatic bilirubin uridine diphosphate-glucuronyl transferase activity and perhaps an abnormality in the function or amount of one or more hepatocyte membrane protein carriers. Accelerated jaundice of the newborn, breast milk jaundice, and jaundice with intestinal obstruction may be present in affected infants. During puberty and beyond, mild fluctuating jaundice, especially with illness, and vague constitutional symptoms are common. Shortened red blood cell survival time in some patients is thought to be caused by reduced activity of enzymes involved in heme biosynthesis (protoporphyrinogen oxidase). Subsidence of hyperbilirubinemia has been achieved in patients by administration of phenobarbital (5–8 mg/kg/d), although this therapy is not justified.

The disease is inherited as an abnormality of the promoter region of uridine diphosphate-glucuronyl transferase-1; however, another factor is necessary for disease expression. The homozygous (16%) and heterozygous states (40%) are common. Males are affected more often than females (4:1). Serum unconjugated bilirubin is generally less than 3–6 mg/dL, although unusual cases may exceed 8 mg/dL. The findings on liver biopsy and most other LFTs are normal except for prolonged indocyanine green and bromosulfophthalein retention. An increase of 1.4 mg/dL or more in the level of unconjugated bilirubin after a 2-day fast (300 kcal/d) is consistent with the diagnosis of Gilbert syndrome. Genetic testing is available but rarely needed. No treatment is necessary.

E. Crigler-Najjar Syndrome

Infants with type I Crigler-Najjar syndrome usually develop rapid severe elevation of unconjugated bilirubin (> 30–40 mg/dL) with neurologic consequences (kernicterus). Conjugation is often present. Prompt recognition of this entity and treatment with exchange transfusions are required, followed by phototherapy. Some patients have no neurologic signs until adolescence or early adulthood, at which time deterioration may occur suddenly. For diagnosis of this condition it is useful to obtain a duodenal bile specimen, which characteristically will be colorless and contain a predominance of unconjugated bilirubin, small amounts of monoconjugates, and only traces of diconjugated bilirubin. Phenobarbital administration does not significantly alter these findings, nor does it lower serum bilirubin levels. The deficiency in uridine diphosphate-glucuronyl transferase-1 is inherited in an autosomal recessive pattern. A combination of phototherapy and cholestyramine may keep bilirubin levels below 25 mg/dL. The use of tin protoporphyrin or tin mesoporphyrin remains experimental. Orlistat therapy may decrease bilirubin in a subset of patients. Liver transplantation is curative and may prevent kernicterus if performed.
early. An auxiliary orthotopic transplantation also relieves the jaundice while the patient retains native liver. Hepatocyte transplantation is experimental.

A milder form (type 2) with both autosomal dominant and recessive inheritance is rarely associated with neurologic complications. Hyperbilirubinemia is less severe, and the bile is pigmented and contains bilirubin monoglucuronide and diglucuronide. Patients with this form respond to phenobarbital with lowering of serum bilirubin levels. An increased proportion of monoconjugated and diconjugated bilirubin in the bile follows phenobarbital treatment. Liver biopsy findings and LFTs are consistently normal in both types.

F. Drug-Induced Hyperbilirubinemia

Vitamin K$_3$ (menadiol) may elevate indirect bilirubin levels by causing hemolysis. Vitamin K$_1$ (phytonadione) can be used safely in neonates. Carbamazepine can cause conjugated hyperbilirubinemia in infancy. Rifampin and antiretroviral protease inhibitors may cause unconjugated hyperbilirubinemia. Other drugs (eg, ceftriaxone, sulfonamides) may displace bilirubin from albumin, potentially increasing the risk of kernicterus—especially in the sick premature infant.

2. Conjugated Noncholestatic Hyperbilirubinemia (Dubin-Johnson Syndrome & Rotor Syndrome)

These diagnoses are suspected when persistent or recurrent conjugated hyperbilirubinemia and jaundice occur and liver function tests are normal. The basic defect in Dubin-Johnson syndrome is in the multiple organic anion transport protein (MRP2) of the bile canaliculus, causing impaired hepatocyte excretion of conjugated bilirubin into bile. A variable degree of impairment in uptake and conjugation complicates the clinical picture. Transmission is autosomal recessive, so a positive family history is occasionally obtained. In Rotor syndrome, the defect lies in hepatic uptake and storage of bilirubin. Bile acids are metabolized normally, so that cholestasis does not occur. Bilirubin values range from 2–5 mg/dL, and other LFTs are normal.

In Rotor syndrome, the liver is normal; in Dubin-Johnson syndrome, it is darkly pigmented on gross inspection and may be enlarged. Microscopic examination reveals numerous dark-brown pigment granules consisting of polymers of epinephrine metabolites, especially in the centrilobular regions. However, the amount of pigment varies within families, and some jaundiced family members may have no demonstrable pigmentation in the liver. Otherwise, the liver is histologically normal. Oral cholecystography fails to visualize the gallbladder in Dubin-Johnson syndrome, but is normal in Rotor syndrome. Differences in the excretion patterns of bromosulfophthalein, in results of DIDA cholecentigraphy, in urinary coproporphyrin I and III levels, and in the serum pattern of monoglucuronide and diglucuronide conjugates of bilirubin can help distinguish between these two conditions. Genotyping of MRP2 is available.

Choleretic agents (eg, UDCA) may help reduce the cholestasis in infants with Dubin-Johnson syndrome.
exposed to HAV by age 10 years, while only 20% are exposed by age 20 years in developed countries.

Antibody to HAV appears within 1–4 weeks of clinical symptoms. Although the great majority of children with infectious hepatitis are asymptomatic or have mild disease and recover completely, some will develop fulminant hepatitis leading to death or requiring liver transplantation.

**Clinical Findings**

**A. History**

Features of the patient’s history may include direct exposure to a previously jaundiced individual, consumption of seafood, contaminated water or imported fruits or vegetables, attendance in a day care center, or recent travel to an area of endemic infection. Following an incubation period of 15–40 days, the initial nonspecific symptoms usually precede the development of jaundice by 5–10 days.

**B. Symptoms and Signs**

Fever, anorexia, vomiting, headache, and abdominal pain are typical symptoms. Dark urine precedes jaundice, which peaks in 1–2 weeks and then begins to subside. The stools may become light or clay-colored during this time. Clinical improvement can occur as jaundice develops. Tender hepatomegaly and jaundice are typically present; splenomegaly is variable.

**C. Laboratory Findings**

Aminotransferases and conjugated and unconjugated bilirubin levels are elevated. The leukocyte count is normal to low; the sedimentation rate is elevated. Serum proteins are generally normal, but an elevation of the γ-globulin fraction (> 2.5 g/dL) can occur and indicates a worse prognosis. Hypoalbuminemia, hypoglycemia, and marked prolongation of prothrombin time (international normalized ratio [INR] > 2.0) are serious prognostic findings. Diagnosis is made by serology. A positive anti-HAV IgM indicates acute disease, whereas IgG anti-HAV persists after recovery.
Percutaneous liver biopsy is rarely indicated. “Balloon cells” and acidophilic bodies are characteristic histologic findings. Liver cell necrosis may be diffuse or focal, with accompanying infiltration of inflammatory cells containing polymorphonuclear leukocytes, lymphocytes, macrophages, and plasma cells, particularly in portal areas. Some bile duct proliferation may be seen in the peribiliary portal areas alongside areas of bile stasis. Regenerative liver cells and proliferation of reticuloendothelial cells are present. Occasionally massive hepatocyte necrosis occurs, portending a bad prognosis.

**Differential Diagnosis**

Before jaundice appears, the symptoms are those of nonspecific viral enteritis. Other diseases with somewhat similar onset include pancreatitis, infectious mononucleosis, leptospirosis, drug-induced hepatitis, Wilson disease, autoimmune hepatitis, and other hepatitis viruses. Acquired CMV disease may also mimic HAV, although lymphadenopathy is usually present in the former.

**Prevention**

Isolation of the patient during initial phases of illness is indicated, although most patients with hepatitis A are non-infectious by the time the disease becomes overt. Stool, diapers, and other fecally stained clothing should be handled with care for 1 week after the appearance of jaundice.

Passive-active immunization of exposed susceptible persons can be achieved by giving standard immune globulin, 0.02–0.04 mL/kg intramuscularly. Illness is prevented in 80–90% of individuals if immune globulin is given within 1–2 weeks of exposure. Alternatively, HAV vaccine can be given following exposure, with equal efficacy at preventing symptomatic HAV infection. Individuals traveling to endemic disease areas should receive HAV vaccine or 0.02–0.06 mL/kg of immune globulin as prophylaxis if there is insufficient time (< 2 weeks) for the initial dose of vaccine. All children older than 12 months with chronic liver disease should receive two doses of HAV vaccine 6 months apart. It is currently recommended that all children 12–23 months of age receive HAV vaccination in the United States.

**Treatment**

No specific treatment measures are required. Sedatives and corticosteroids should be avoided. At the start of the illness, a light diet is preferable. During the icteric phase, lower-fat foods may diminish gastrointestinal symptoms but do not affect overall outcome. Drugs and elective surgery should be avoided.

**Prognosis**

Ninety-nine percent of children recover without sequelae. In rare cases of fulminant hepatitis, the patient may die in 5 days or may survive as long as 1–2 months without liver transplantation. The prognosis is poor if hepatic coma or ascites develop; orthotopic liver transplantation is indicated under these circumstances. Incomplete resolution can cause a prolonged hepatitis; however, resolution invariably occurs without long-term hepatic sequelae. Rare cases of aplastic anemia following acute infectious hepatitis have been reported. A benign relapse of symptoms may occur in 10–15% of cases after 6–10 weeks of apparent resolution.

infected patients early and correlates with active virus replication. Persistence of HBeAg is a marker of infectivity, whereas the appearance of anti-HBe generally implies termination of viral replication. However, HBV mutant viruses (precore mutant) may replicate with negative HBeAg tests and positive tests for anti-HBe antibody. Other serologic markers indicating viral replication include the presence of HBV DNA polymerase and circulating HBV DNA.

Clinical Findings

A. Symptoms and Signs

Symptoms of acute hepatitis B infection include slight fever (which may be absent) and mild gastrointestinal upset. Visible jaundice is usually the first significant finding. It is accompanied by darkening of the urine and pale or clay-colored stools. Many patients, particularly infants, are asymptomatic. Hepatomegaly is frequently present. Occasionally a symptom complex (caused by antigen-antibody complexes) of macular rash, urticarial lesions, and arthritis antedates the appearance of icterus. Occasionally, HBV infection presents as a glomerulonephritis or nephrotic syndrome from immune complexes. When acquired vertically at birth, the disease is usually asymptomatic despite ongoing liver injury.

B. Laboratory Findings

To diagnose acute HBV infection, the HBsAg and anti-HBc IgM are the only tests needed. To document recovery, immunity, or response to the HBV vaccine, the anti-HBs is useful. To document previous HBV infection, the anti-HBc is most useful. If HBsAg persists after 8 weeks in acute infections, it may signify a chronic infection, although chronic infection is defined as lasting 6 months or more. Vertical transmission to newborns is documented by positive HBsAg or HBsAb in the liver, and ground-glass appearance to hepatocytes may be present. Renal involvement may be suspected on the basis of urinary findings suggesting glomerulonephritis or nephrotic syndrome.

Differential Diagnosis

The differentiation between HAV and HBV disease is made easier by a history of parenteral exposure, an HBsAg-positive parent, or an unusually long period of incubation. HAV and hepatitis C virus (HCV) infection or Epstein-Barr virus (EBV) infection are differentiated serologically. The history may suggest a drug-induced hepatitis, especially if a serum sickness prodrome is reported. Autoimmune hepatitis, Wilson disease, hemochromatosis, nonalcoholic fatty liver disease, and α1-antitrypsin deficiency should also be considered. Drug-induced hepatitis is diagnosed if there is a history of specific drug exposure; autoimmune hepatitis is diagnosed if autoimmune markers are present; Wilson disease is diagnosed if ceruloplasmin levels are abnormal; hemochromatosis is diagnosed if transferrin saturation is high; α1-antitrypsin deficiency is diagnosed if serum α1-antitrypsin concentration is decreased; and steatohepatitis is diagnosed if liver biopsy findings are suggestive.

Prevention

Control of hepatitis B in the population is based on screening of blood donors and pregnant women, use of properly sterilized needles and surgical equipment, avoidance of sexual contact with carriers, and vaccination of all infants and adolescents, as well as household contacts, sexual partners, medical personnel, and those at high risk. Universal immunization of all infants born in the United States and of adolescents is now recommended, as it is in most other countries. The vaccine is highly effective for preexposure prophylaxis. (See Chapter 9.) For postexposure prophylaxis, administration of HBIG (0.06 mL/kg intramuscularly, given as soon as possible after exposure, up to 7 days) and initiation of vaccination are recommended. The risk of vertical transmission is dramatically reduced with the combination of postpartum vaccination and immunoprophylaxis.

Treatment

Supportive measures such as bed rest and a nutritious diet are used during the active symptomatic stage of disease. Corticosteroids are contraindicated. No other treatment is needed for acute HBV infection. For patients with progressive disease (chronic hepatitis with fibrosis), there are currently two treatment options. Treatment with α-interferon (5–6 million U/m² body surface area injected subcutaneously three times a week for 4–6 months) inhibits viral replication in 30–40% of patients, normalizes the ALT level, and leads to the disappearance of HBeAg and the appearance of anti-HBe. Side effects are common. Younger children may respond better than older children. Orally administered lamivudine therapy (3 mg/kg/d up to 100 mg/d for 12 months) leads to a successful response in 25% of treated children, with minimal side effects. However, resistant organisms can emerge. Pegylated interferon, several oral antiviral agents, and combination therapy are promising options being tested in children. Asymptomatic HBsAg carriers (normal serum ALT, no hepatomegaly) do not respond to either therapy. Liver transplantation is successful in acute fulminant hepatitis B; however, reinfection is common following liver transplantation for chronic hepatitis B. Chronic HBig therapy or lamivudine therapy reduces recurrence after transplantation.

Prognosis

The prognosis is good, although fulminant hepatitis or chronic hepatitis and cirrhosis may supervene in up to 10% of patients. The course of the acute disease is variable, but
jaundice seldom persists for more than 2 weeks. HBsAg disappears in 95% of cases at the time of clinical recovery. Persistent asymptomatic infection may occur, particularly in children with vertical transmission, Down syndrome, or leukemia, and in those undergoing chronic hemodialysis. Persistence of neonatally acquired HBsAg occurs in 70–90% of infants without immunoprophylaxis or vaccination, and the presence of HBeAg in the HBsAg carrier indicates ongoing viral replication. However, 1–2% of children infected at birth will show spontaneous seroconversion of HBeAg each year. If HBV infection is acquired later in childhood, HBV is cleared and recovery occurs in 90–95% of patients. Chronic hepatitis B disease predisposes the patient to development of hepatocellular carcinoma. Once chronic HBV infection is established, surveillance for development of hepatocellular carcinoma with serum α-fetoprotein is performed biannually and ultrasonography yearly. Routine HBV vaccination of newborns in endemic countries has reduced the incidence of fulminant hepatic failure, chronic hepatitis, and hepatocellular carcinoma in children.

**HEPATITIS C**

**General Considerations**

Hepatitis C virus (HCV) virus is the most common cause of non-B chronic hepatitis (90% of post-transfusion hepatitis cases) (see Table 21–6). Risk factors in adults and older children include illicit use of intravenous drugs (40%), occupational or sexual exposure (10%), and transfusions (10%); 30% of cases have no known risk factors. In children, most cases are now associated with transmission from an infected mother or other household transmission. In the past, children with hemophilia or on chronic hemodialysis were at significant risk. The risk from transfused blood products has diminished greatly (from 1–2:100 to 1:100,000 units of blood) since the advent of blood testing for ALT and anti-HCV. HCV infection has also been caused by contaminated immune serum globulin preparations. Vertical transmission from HCV-infected mothers occurs more commonly with mothers who are HIV-positive (15–20%) compared with those who are HIV-negative (5–6%). About 0.4% of adolescents and 1.5% of adults in the United States have serologic evidence of infection. Vertically infected infants often have elevated ALT levels, but do not appear ill; long-term outcome is unknown, however 20–30% of infants recover completely. Transmission of the virus from breast milk is probably rare. HCV rarely causes fulminant hepatitis in children or adults in Western countries, but different serotypes do so in Asia.

HCV is a single-stranded RNA virus in the flavivirus family. At least seven genotypes of HCV exist. Several well-defined HCV antigens are the basis for serologic antibody tests. The third-generation enzyme-linked immunosorbent assay (ELISA) test for anti-HCV is highly accurate. Anti-HCV is generally present when symptoms occur; however, test results may be negative in the first few months of infection. The presence of HCV RNA in serum indicates active infection.

**Clinical Findings**

**A. Symptoms and Signs**

The incubation period is 1–5 months, with insidious onset of symptoms. Many childhood cases, especially those acquired vertically, are asymptomatic despite development of chronic hepatitis. Flulike prodromal symptoms and jaundice occur in less than 25% of cases. Hepatosplenomegaly may or may not be evident in chronic hepatitis. Ascites, clubbing, palmar erythema, or spider angiomas are rare and indicate progression to cirrhosis.

**B. Laboratory Findings**

Fluctuating mild to moderate elevations of aminotransferases over long periods are characteristic of chronic HCV infection. Diagnosis is established by the presence of anti-HCV (third-generation ELISA) confirmed by the radioimmunoblot assay or HCV RNA by PCR. Anti-HCV is acquired passively at birth from infected mothers and cannot be used to confirm disease in the neonate for the first 15 months. HCV RNA testing should be performed in suspected cases. Results of this test may be negative in the first month of life, but become positive by 4 months.

Percutaneous liver biopsy should be considered in chronic cases. Histologic examination shows portal triaditis with chronic inflammatory cells, occasional lymphocyte nodules in portal tracts, mild macrovesicular steatosis, and variable bridging necrosis, fibrosis, and cirrhosis; most children have only mild to moderate fibrosis on liver biopsy. Cirrhosis in adults generally requires 20–30 years of chronic HCV infection, but it has occasionally developed sooner in children.

**Differential Diagnosis**

HCV disease should be distinguished from HAV and HBV disease by serologic testing. Other causes of cirrhosis in children should be considered in cases of chronic illness,
such as Wilson disease or \( \alpha_1 \)-antitrypsin deficiency. Chronic hepatitis may also be caused by drug reactions, autoimmune disease, or steatohepatitis.

### Treatment

Treatment of acute HCV hepatitis is supportive. Indications for treatment of chronic infection will be determined by current clinical trials. Chronic hepatitis caused by HCV responds to combined interferon-\( \alpha \) (3 million U/m² three times a week for 6–12 months) and ribavirin (15 mg/kg/d), with sustained response rates of 30–50%. The response is poorer in those who have infections with genotype 1a or 1b and very good for genotypes 2 and 3. Long-acting (pegylated) interferon (with or without ribavirin), which has been studied in adults, is more effective, with sustained response rates up to 60–70%. This therapy is being tested in children. End-stage liver disease secondary to HCV responds well to liver transplantation, although reinfection is common and is occasionally rapidly progressive. Pre- and post-transplant antiviral therapy may reduce the risk of reinfection. There is no vaccine, and no benefit from using immune globulin in infants born to infected mothers. Elective cesarean delivery of HCV-infected pregnant women with a high titer of circulation may lessen the likelihood for vertical transmission.

### Prognosis

In adults, 70–80% of HCV patients develop chronic hepatitis, and cirrhosis develops in 20% of those with chronic infection for 10–30 years. Alcohol intake, and concomitant obesity and fatty liver, increase this risk. HCV is now the leading indication for liver transplantation in adults. A strong association exists between chronic HCV disease and the development of hepatocellular carcinoma after as little as 15 years. The outcome in children is less well defined, although cirrhosis may develop rapidly in rare cases or after decades. About 50% of children infected by transfusion may be infected with the virus: Rate of infection and risk factors. Scand J Infect Dis 2005;37:350 [PMID: 16051571].

### Hepatitis D (Delta Agent)

The hepatitis D virus (HDV) is a 35-nm defective virus that requires a coat of HBsAg to be infectious (see Table 21–6). Thus, HDV infection can occur only in the presence of HBV infection. In developing countries, transmission is by intimate contact; in western countries, by parenteral exposure. HDV is rare in North America. HDV can infect simultaneously with HBV, causing acute hepatitis, or can superinfect a patient with chronic HBV infection, predisposing the individual to chronic hepatitis or fulminant hepatitis. In children, the association between chronic HDV coinfection with HBV and chronic hepatitis and cirrhosis is strong. Vertical HDV transmission is rare. The diagnosis of HDV is made by anti-HDV IgM or detection of HDV by PCR. Treatment is directed at therapy for HBV infection or for fulminant hepatic failure.

### Hepatitis E

Hepatitis E virus (HEV) infection is a cause of enterically transmitted, epidemic non-A, non-B hepatitis (see Table 21–6). It is rare in the United States. HEV is a calicivirus-like agent that is transmitted via the fecal-oral route. It occurs predominantly in developing countries in association with waterborne epidemics, and has only a 3% secondary attack rate in household contacts. Areas reporting epidemics include Southeast Asia, China, the Indian subcontinent, the Middle East, northern and western Africa, Mexico, and Central America. Its clinical manifestations resemble HAV infection except that symptomatic disease is rare in children, more common in adolescents and adults, and is associated with a high mortality (10–20%) in pregnant women, particularly in the third trimester. Diagnosis is established by detecting anti-HEV antibody. The outcome in nonpregnant individuals is benign, with no chronic hepatitis or chronic carrier state reported. A recombinant vaccine is being tested. There is no effective treatment.

### Other Hepatitis Viruses

Other undiscovered viruses may be the cause of cases of fulminant hepatitis in children that can be associated with the development of aplastic anemia in a small proportion of patients recovering from hepatitis and in 10–20% of those...
undergoing liver transplantation for indeterminate fulminating hepatitis. Parvovirus has been associated with fulminating hepatitis; the prognosis is relatively good in children. Infectious mononucleosis (EBV) is commonly associated with acute hepatitis. CMV, adenovirus, herpes simplex virus, HHV-6, HIV, brucella, and leptospirosis are other infectious causes of acute hepatitis.

> **Clinical Findings**

In some patients, the disease proceeds in a rapidly fulminant course with deepening jaundice, coagulopathy, hyperammonemia, ascites, a rapidly shrinking liver, and progressive coma. Terminally, AST and ALT, which were greatly elevated (2000–10,000 U/L), may improve at the time when the liver is getting smaller and undergoing massive necrosis and collapse. Some patients start with a course typical of benign hepatitis and then suddenly become severely ill during the second week of the disease. Fever, anorexia, vomiting, and abdominal pain may be noted, and worsening of LFTs parallels changes in sensorium or impending coma. Hyperreflexia and a positive extensor plantar response are seen. A characteristic breath odor (fetor hepaticus) is present. A severe coagulopathy precedes impairment of renal function, manifested by either oliguria or anuria, which is an ominous sign. Characteristic laboratory findings include elevated serum bilirubin levels (usually > 15–20 mg/dL), sustained very high AST and ALT (> 3000 U/L) that may decrease terminally, low serum albumin, hypoglycemia, and prolonged prothrombin time and INR. Blood ammonia levels become elevated, whereas blood urea nitrogen is often very low. Hyperpnea is frequent, and mixed respiratory alkalosis and metabolic acidosis are present.

**General Considerations**

Acute liver failure (ALF) is defined as acute liver dysfunction resulting in hepatic coma and coagulopathy (INR > 2.0) within 6 weeks after onset. In young children, encephalopathy may be difficult to detect or absent. Mortality is approximately 50% in children (without liver transplantation). An unusually virulent infectious agent or aggressive host immune response is postulated in many cases. In the first few weeks of life, ALF can be caused by herpes simplex, enteroviruses, adenovirus, galactosemia, fructose intolerance, tyrosinemia, neonatal iron storage disease, respiratory chain and fatty acid oxidation defects, familial erythrophagocytic histiocytosis, bile acid synthesis defects, and peroxisomal diseases. In older infants and children, the most common identified diagnoses are idiopathic, acetaminophen toxicity, autoimmune hepatitis, and infections. HBV, parvovirus, and HEV are sometimes causative. HAV rarely is responsible in the United States. Patients with immunologic deficiency diseases and those receiving immunosuppressive drugs are vulnerable to herpesviruses. In children with HIV infection, nucleoside reverse transcriptase inhibitors have triggered lactic acidosis and liver failure. In patients with underlying respiratory chain defects, valproic acid may trigger ALF. In older children, Wilson disease, acute fatty liver of pregnancy, Reye syndrome, drugs (eg, acetaminophen, anesthetic agents, valproic acid) or toxins (eg, poisonous mushrooms, herbs, “ecstasy”), leukemia, and cardiac dysfunction must also be considered. Some 30–40% of cases in children are without identifiable cause and labeled indeterminate.

**Differential Diagnosis**

Infectious, autoimmune, metabolic, and drug or toxin causes are most common. Patients with Reye syndrome or urea cycle defects are typically anicteric. Wilson disease, autoimmune hepatitis, acute leukemia, cardiomyopathy, and Budd-Chiari syndrome should be considered. Acetaminophen overdose, herbal remedies, and other toxins (eg, “ecstasy”) need to be considered even if the history is negative.

**Complications**

The development of renal failure and depth of hepatic coma determine the prognosis. Patients in grade 4 coma (unresponsiveness to verbal stimuli, decorticate or decerebrate posturing) rarely survive without transplantation and may have residual central nervous system deficits. Cerebral edema, which usually accompanies coma, is frequently the cause of death. Extreme prolongation of prothrombin time or INR greater than 4 predicts poor recovery except with acetaminophen overdose. Sepsis, hemorrhage, renal failure, or cardiorespiratory arrest is a common terminal event. The rare survivor of advanced disease without transplantation may have residual fibrosis or even cirrhosis.

**Treatment**

The most effective therapy is excellent critical care. Several therapies have failed to affect outcome, including exchange transfusion, plasmapheresis with plasma exchange, total body washout, charcoal hemoperfusion, and hemodialysis using a special high-permeability membrane. Hyperammonemia and bleeding should be controlled. Extracorporeal hepatic support devices are being developed to help bridge patients to liver transplantation or allow for liver regeneration. Orthotopic liver transplantation is successful in 60–85% of cases; however, patients in grade 4 coma may not always recover cerebral function. Therefore, patients in ALF should be transferred prior to the development of hepatic coma to centers where liver transplantation can be performed. Criteria for deciding when to perform transplantation are not firmly established; however, serum bilirubin over 20 mg/dL, INR greater than 4, and factor V levels less than 20% indicate a poor prognosis. Living related donors may be required for transplantation in a timely fashion. The selection of donors for transplantation in this group of patients is challenging. The survival rate in patients who undergo liver transplantation is 60–85%.

**AUTOIMMUNE HEPATITIS**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Acute or chronic hepatitis.
- Hypergammaglobulinemia.
- Positive antinuclear antibodies (ANA), anti-smooth muscle antibodies (ASMA), anti-liver-kidney microsomal (LKM) antibodies, or anti-soluble liver antibodies (SLA).

**General Considerations**

Autoimmune hepatitis (AIH) is most common in adolescent girls, although it occurs at all ages and in either sex. Rarely, AIH evolves from drug-induced hepatitis (eg, minocycline) or may develop in conjunction with such diseases as ulcerative colitis, Sjögren syndrome, or autoimmune hemolytic anemia. Wilson disease, α1-antitrypsin deficiency, cystic fibrosis, and bile acid synthesis defects may present similarly as chronic hepatitis. A positive HBsAg test implicates HBV, and a positive HCV PCR suggests HCV infection. Positive autoantibodies, elevated serum IgG, and systemic manifestations (eg, arthralgia, weight loss, acne, and amenorrhea) are characteristic of AIH.

A genetic susceptibility to development of this entity is suggested by the increased incidence of the histocompatibility antigens HLA-A1 and HLA-B8. Increased autoimmune...
disease in families of patients and a high prevalence of seroimmunologic abnormalities have been noted in relatives. Occasionally patients have an “overlap syndrome” of AIH and primary sclerosing cholangitis.

**Clinical Findings**

Fever, malaise, recurrent or persistent jaundice, skin rash, arthritis, amenorrhea, gynecomastia, acne, pleurisy, pericarditis, or ulcerative colitis may be found in the history of these patients, or asymptomatic hepatomegaly or splenomegaly may be found on examination. Occasionally patients present in acute liver failure. Cutaneous signs of chronic liver disease may be noted (eg, spider angiomas, palmar erythema, and digital clubbing). Hepatosplenomegaly is frequently present. LFTs reveal moderate elevations of serum bilirubin, AST, ALT, and serum alkaline phosphatase. Serum albumin may be low. Serum IgG levels are strikingly elevated (in the range of 2–6 g/dL). Low levels of C3 complement have been reported. Three subtypes of disease have been described based on autoantibodies present: type 1—anti-smooth muscle (antiactin); type 2—anti-LKM (anti–cytochrome P-450); and type 3—anti-SLA.

Histologic examination of liver biopsy specimens shows loss of the lobular limiting plate, and interface hepatitis (“piecemeal” necrosis). Portal fibrosis, an inflammatory reaction of lymphocytes and plasma cells in the portal areas and perivascularly, and some bile duct and Kupffer cell proliferation and pseudolobule formation may be present. Cirrhosis may exist at diagnosis in up to 50% of patients.

**Differential Diagnosis**

Laboratory and histologic findings differentiate other types of chronic hepatitis (eg, HBV, HCV, and HDV infection; steatohepatitis; Wilson disease; α1-antitrypsin deficiency; primary sclerosing cholangitis). Primary sclerosing cholangitis occasionally presents in a manner similar to AIH, including the presence of autoantibodies. Wilson disease and α1-antitrypsin deficiency must be excluded if HBV and HCV studies are negative. Anti-HCV antibodies can be falsely positive and should be confirmed by HCV PCR. Drug-induced (minocycline, isoniazid, methyldopa, pemoline) chronic hepatitis should be ruled out.

**Complications**

Untreated disease that continues for months to years eventually results in postsclerosing cirrhosis, with complications of portal hypertension. Persistent malaise, fatigue, amenorrhea, and anorexia parallel disease activity. Bleeding from esophageal varices and development of ascites usually usher in hepatic failure.

**Treatment**

Corticosteroids (prednisone, 2 mg/kg/d) decrease the mortality rate during the early active phase of the disease. Azathioprine or 6-mercaptopurine (6MP), 1–2 mg/kg/d, is of value in decreasing the side effects of long-term corticosteroid therapy but should not be used alone during the induction phase of treatment. Steroids are reduced over a 3- to 12-month period, and azathioprine is continued for 1–2 years if AST and ALT remain consistently normal. Liver biopsy is performed before stopping azathioprine therapy; if inflammation persists, then azathioprine is continued. Thiopurine methyltransferase activity should be assessed prior to starting azathioprine, to prevent extremely high blood levels and severe bone marrow toxicity. Relapses are treated similarly. Many patients require chronic azathioprine or 6MP therapy. UCDA, cyclosporine, tacrolimus, or methotrexate may be helpful in poorly responsive cases. Mycophenolate mofetil can be substituted for azathioprine, but it is more expensive. Liver transplantation is indicated when disease progresses to decompensated cirrhosis despite therapy or in unresponsive cases presenting in acute liver failure. Steroid therapy may be lifesaving in those presenting in acute liver failure.

**Prognosis**

The overall prognosis for AIH is improved significantly with early therapy. Some studies report cures (normal histologic findings) in 15–20% of patients. Relapses (seen clinically and histologically) occur in 40–50% of patients after cessation of therapy; remissions follow repeat treatment. Survival for 10 years is common despite residual cirrhosis. Of children with AIH, 20–50% eventually require liver transplantation. Complications of portal hypertension (bleeding varices, ascites, spontaneous bacterial peritonitis, and hepatopulmonary syndrome) require specific therapy. Liver transplantation is successful 70–90% of the time. Disease recurs after transplantation 10–50% of the time and is treated similarly to pretransplant disease.

**Nonalcoholic Fatty Liver Disease**

**Essentials of Diagnosis & Typical Features**

- Hepatomegaly in patient with BMI > 95th percentile.
- Elevated ALT > AST.
- Detection of fatty infiltration of the liver on ultrasound.
- Histologic evidence of fat in the liver.
- Insulin resistance.

Nonalcoholic fatty liver disease (NAFLD) is increasingly diagnosed in children. Patients with NAFLD present with asympto-
matic soft hepatomegaly. If nonalcoholic steatohepatitis (NASH) is present, mild to moderately elevated aminotransferases (2–10 times the upper limit of normal) are also present. ALT is frequently higher than AST. Alkaline phosphatase and GGT may be mildly elevated, but bilirubin is normal. Ultrasonography or CT scanning indicates fat density in the liver. Liver biopsy shows micro- or macrovesicular steatosis in simple NAFLD, with the addition of portal tract inflammation, Mallory bodies, and variable degrees of portal fibrosis to cirrhosis in NASH. Most cases are associated with overweight state or type 2 diabetes mellitus. The prevalence of NAFLD is related to the prevalence of obesity in the population. The prevalence is estimated at 10% for children and adolescents with significant racial and ethnic variability. One to 3% of adolescents in the United States may have NASH, based on the observation that 15–25% of American adolescents are overweight or obese and that roughly 40% will have NAFLD and 10% will have NASH. Steatohepatitis is also associated with Wilson disease, hereditary fructose intolerance, tyrosinemia, HCV hepatitis, cystic fibrosis, fatty acid oxidation defects, kwashiorkor, Reye syndrome, respiratory chain defects, and toxic hepatopathy (ethanol and others). Treatment is weight reduction and exercise for obesity or treatment for the other causes. A pilot trial suggests that vitamin E may be helpful and is currently under study. In addition, improved control of insulin resistance with metformin or pioglitazone is also under study in NASH. Cirrhosis and liver failure have been described in adults with this disease.

**α1-ANTITRYPSIN DEFICIENCY LIVER DISEASE**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Serum α1-antitrypsin level < 50–80 mg/dL.
- Identification of a specific protease inhibitor (Pi) phenotype (PiZZ, PiSZ) or genotype.
- Detection of diastase-resistant glycoprotein deposits in periportal hepatocytes.
- Histologic evidence of liver disease.
- Family history of early-onset pulmonary disease or liver disease.

**General Considerations**

The disease is caused by a deficiency in α1-antitrypsin, a protease inhibitor (Pi) system, predisposing patients to chronic liver disease and an early onset of pulmonary emphysema. It is most often associated with the Pi phenotypes ZZ and SZ. Heterozygotes may have a slightly higher incidence of liver disease. The exact relationship between low levels of serum α1-antitrypsin and the development of liver disease is unclear. Emphysema develops because of a lack of inhibition of neutrophil elastase, which destroys pulmonary connective tissue. The accumulation of misfolded aggregates of α1-antitrypsin protein in the liver causes the liver injury by unclear mechanisms. Although all patients with the ZZ genotype eventually have antitrypsin inclusions in hepatocytes, only about 15–20% develop significant liver disease. Thus another genetic or environmental modifier must be involved. An associated abnormality in the microsomal disposal of accumulated aggregates may contribute to the liver disease phenotype.

About 10–20% of affected individuals present with neonatal cholestasis. About 10% of individuals with α1-antitrypsin deficiency have clinically significant liver injury by age 18 years. Very few children have significant pulmonary involvement. Most affected children are completely asymptomatic, with no laboratory or clinical evidence of liver or lung disease.

**Clinical Findings**

**A. Symptoms and Signs**

α1-Antitrypsin deficiency should be considered in all infants with neonatal cholestasis. Serum GGT is usually, but not always, elevated. Jaundice, acholic stools, and malabsorption may also be present. Infants are often small for gestational age, and hepatosplenomegaly may be present. The family history may be positive for emphysema or cirrhosis.

In older children, hepatomegaly or physical findings suggestive of cirrhosis and portal hypertension, especially in the face of a negative history of liver disease, should always lead one to consider α1-antitrypsin deficiency. Recurrent pulmonary disease (bronchitis, pneumonia) may be present in a few older children.

**B. Laboratory Findings**

Levels of the α1-globulin fraction may be less than 0.2 mg/dL on serum protein electrophoresis. α1-Antitrypsin level is low (<50–80 mg/dL) in homozygotes (ZZ). Specific Pi phenotyping should be done to confirm the diagnosis. Genotyping is also available. LFTs often reflect underlying hepatic pathologic changes. Hyperbilirubinemia (mixed) and elevated aminotransferases, alkaline phosphatase, and GGT are present early. Hyperbilirubinemia generally resolves, while aminotransferase and GGT elevation may persist. Signs of cirrhosis and hypersplenism may develop even when LFTs are normal.

Liver biopsy findings after age 6 months show diastase-resistant, periodic acid–Schiff staining intracellular globules, particularly in periportal zones. These may be absent prior to age 6 months, but when present are characteristic of α₁-antitrypsin deficiency.

**Differential Diagnosis**

In newborns, other specific causes of neonatal cholestasis need to be considered, including biliary atresia. In older children, other causes of insidious cirrhosis (eg, HBV or HCV infection, autoimmune hepatitis, Wilson disease, cystic fibrosis, hemochromatosis, and glycogen storage disease) should be considered.

**Complications**

Of all infants with PiZZ α₁-antitrypsin deficiency, only 15–20% develop liver disease in childhood, and many have clinical recovery. The complications of portal hypertension, cirrhosis, and chronic cholestasis predominate in affected children. Occasionally, children develop paucity of interlobular bile ducts.

Early-onset pulmonary emphysema occurs in young adults (age 30–40 years), particularly in smokers. An increased susceptibility to hepatocellular carcinoma has been noted in cirrhosis associated with α₁-antitrypsin deficiency.

**Treatment**

There is no specific treatment for the liver disease of this disorder. Replacement of the protein by transfusion therapy is used to prevent or treat pulmonary disease in affected adults. The neonatal cholestatic condition is treated with choleretics, medium-chain triglyceride-containing formula, and water-soluble preparations of fat-soluble vitamins (see Table 21–4). UCDA may reduce AST, ALT, and GGT, but its effect on outcome is unknown. Portal hypertension, esophageal bleeding, ascites, and other complications are treated as described elsewhere. Hepatitis A and B vaccines should be given to children with α₁-antitrypsin deficiency. Genetic counseling is indicated when the diagnosis is made. Diagnosis by prenatal screening is possible. Liver transplantation, performed for development of end-stage liver disease, cures the deficiency. Passive and active cigarette smoke exposure should be eliminated to help prevent pulmonary manifestations, and obesity should be avoided.

**Prognosis**

Of those patients presenting with neonatal cholestasis, approximately 10–25% will need liver transplantation in the first 5 years of life, 15–25% during childhood or adolescence, and 50–75% will survive into adulthood with variable degrees of liver fibrosis. A correlation between histologic patterns and clinical course has been documented in the infantile form of the disease. Liver failure can be expected 5–15 years after development of cirrhosis. Recurrence or persistence of hyperbilirubinemia along with worsening coagulation studies indicates the need for evaluation for possible liver transplantation. Decompensated cirrhosis caused by this disease is an excellent indication for liver transplantation; the survival rate should reach 80–90%. Pulmonary involvement is prevented by liver transplantation.

**Wilson Disease (Hepatolenticular Degeneration)**

**Essentials of Diagnosis & Typical Features**

- Acute or chronic liver disease.
- Deteriorating neurologic status.
- Kayser-Fleischer rings.
- Elevated liver copper.
- Abnormalities in levels of ceruloplasmin and serum and urine copper.

**General Considerations**

Wilson disease is caused by mutations in the gene ATP7B on chromosome 13 coding for a specific P-type adenosine triphosphatase involved in copper transport. This results in impaired bile excretion of copper and incorporation of copper into ceruloplasmin by the liver. The accumulated hepatic copper causes oxidant (free-radical) damage to the liver. Subsequently, copper accumulates in the basal ganglia and other tissues. The disease should be considered in all children older than age 3 years with evidence of liver disease (especially with hemolysis) or with suggestive neurologic signs. A family history is often present, and 25% of patients are identified by screening asymptomatic homozygous family members. The disease is autosomal recessive and occurs in 1:30,000 live births in all populations.

**Clinical Findings**

**A. Symptoms and Signs**

Hepatic involvement may be fulminant; may present as an acute hepatitis; may masquerade as chronic liver disease; or
may progress insidiously to postnecrotic cirrhosis. Findings include jaundice; hepatomegaly early in childhood; splenomegaly; Kayser-Fleischer rings; and later onset of neurologic manifestations, such as tremor, dysarthria, and drooling beginning after age 10 years. Deterioration in school performance is often the earliest neurologic expression of disease. Psychiatric symptoms may also occur. The Kayser-Fleischer rings can sometimes be detected by unaided visual inspection as a brown band at the junction of the iris and cornea, but slit-lamp examination is always necessary. Absence of Kayser-Fleischer rings does not exclude this diagnosis.

**B. Laboratory Findings**

The laboratory diagnosis is sometimes difficult. Serum ceruloplasmin levels (measured by the oxidase method) are usually less than 20 mg/dL. (Normal values are 23–43 mg/dL.) Low values, however, occur normally in infants younger than 3 months, and in at least 10% of homozygotes the levels may be within the lower end of the normal range (20–30 mg/dL), particularly if immunoassays are used to measure ceruloplasmin. Rare patients with higher ceruloplasmin levels have been reported. Serum copper levels are low, but the overlap with normal is too great for satisfactory discrimination. In acute fulminant Wilson disease serum copper levels are elevated markedly, owing to hepatic necrosis and release of copper. The presence of anemia, hemolysis, very high serum bilirubin levels (> 20–30 mg/dL), low alkaline phosphatase, and low uric acid are characteristic of acute Wilson disease. Urine copper excretion in children older than 3 years is normally less than 30 mcg/d; in Wilson disease, it is generally greater than 150 mcg/d. Finally, the tissue content of copper from a liver biopsy, normally less than 50 mcg/g dry tissue, is greater than 250 mcg/g in Wilson disease.

Glycosuria and aminoaciduria have been reported. Hemolysis and gallstones may be present; bone lesions simulating those of osteochondritis dissecans have also been found. The coarse nodular cirrhosis, steatosis, and glycogenated nuclei seen on liver biopsy may distinguish Wilson disease from other types of cirrhosis. Early in the disease, vacuolation of liver cells, steatosis, and lipofuscin granules can be seen, as well as Mallory bodies. The presence of Mallory bodies in a child is strongly suggestive of Wilson disease. Stains for copper may sometimes be negative despite high copper content in the liver. Therefore, liver copper levels must be determined biochemically on biopsy specimens. Electron microscopy findings of abnormal mitochondria may be helpful.

**Differential Diagnosis**

During the icteric phase, acute viral hepatitis, α1-antitrypsin deficiency, autoimmune hepatitis, Indian childhood cirrhosis, and drug-induced hepatitis are the usual diagnostic possibilities. Nonalcoholic steatohepatitis may have similar histology and be confused with Wilson disease in overweight patients. Later, other causes of cirrhosis and portal hypertension require consideration. Laboratory testing for serum ceruloplasmin, 24-hour urine copper excretion, liver copper concentration, and a slit-lamp examination of the cornea will differentiate Wilson disease from the others. Urinary copper excretion during penicillamine challenge (500 mg twice a day in the older child or adult) may help differentiate Wilson disease from other causes. Genetic testing may be necessary in confusing cases. Other copper storage diseases that occur in early childhood include Indian childhood cirrhosis, Tyrolean childhood cirrhosis, and idiopathic copper toxicosis. However, ceruloplasmin concentrations are normal in these conditions.

**Complications**

Progressive liver disease, postnecrotic cirrhosis, hepatic coma, progressive neurologic degeneration, and death are the rule in the untreated patient. The complications of portal hypertension (variceal hemorrhage, ascites) are poorly tolerated by these patients. Progressive degenerating central nervous system disease and terminal aspiration pneumonia are common in untreated older people. Acute hemolytic disease may result in acute renal failure and profound jaundice as part of the presentation of fulminant hepatitis.

**Treatment**

Copper chelation with d-penicillamine or trientine hydrochloride, 1000–2000 mg/d orally, is the treatment of choice, whether or not the patient is symptomatic. The target dose for children is 20 mg/kg/d; begin with 250 mg/d and increase the dose weekly by 250 mg increments. Strict dietary restriction of copper intake is not practical. Supplementation with zinc acetate (25–50 mg orally, three times daily) may reduce copper absorption. Copper chelation is continued for life, although doses may be reduced transiently at the time of surgery or early in pregnancy. Vitamin B6 (25 mg) is given daily during therapy with penicillamine to prevent optic neuritis. In some countries, after a clinical response to penicillamine or trientine, zinc therapy is substituted and continued for life. Tetrathiomolybdate is being tested as an alternative therapy. Noncompliance with the drug regimen can lead to sudden fulminant liver failure and death.

Liver transplantation is indicated for all cases of acute fulminant disease with hemolysis and renal failure, progressive hepatic decompensation despite several months of penicillamine, and severe progressive hepatic insufficiency in patients who unadvisedly discontinue penicillamine, trientine, or zinc therapy.

**Prognosis**

The prognosis of untreated Wilson disease is poor. Without liver transplantation, all patients with the fulminant presentation succumb. Copper chelation reduces hepatic copper content, reverses many of the liver lesions, and can stabilize
the clinical course of established cirrhosis. Neurologic symptoms generally respond to therapy. All siblings should be immediately screened and homozygotes given treatment with copper chelation or zinc acetate therapy, even if asymptomatic. Genetic testing (haplotype analysis or genotyping) is available clinically if there is any doubt about the diagnosis and for family members.

Cirrhosis is a histologically defined condition of the liver characterized by diffuse hepatocyte injury and regeneration, an increase in connective tissue (bridging fibrosis), and disorganization of the lobular and vascular architecture (regenerative nodules). It may be micronodular or macro- nodular in appearance. It is the vasculature distortion that leads to increased resistance to blood flow, producing portal hypertension and its consequences.

Many liver diseases may progress to cirrhosis. In children, the two most common forms of cirrhosis are postnecrotic and biliary, with different causes, symptomatology, and treatment requirements. Both forms can eventually lead to liver failure and death.

In the pediatric population, postnecrotic cirrhosis is often a result of acute or chronic liver disease (eg, idiopathic neonatal giant-cell hepatitis, viral hepatitis [HBV, HCV], autoimmune or drug-induced hepatitis); more recently, NAFLD; or certain inborn errors of metabolism (see Table 21–5). Cirrhosis is an exceptional outcome of HAV infection and only follows massive hepatic necrosis. The evolution to cirrhosis may be insidious, with no recognized icteric phase, as in some cases of HBV or HCV infection, Wilson disease, hemochromatosis, or α1-antitrypsin deficiency. At the time of diagnosis of cirrhosis, the underlying liver disease may be active, with abnormal LFTs; or it may be quiescent, with normal LFTs. Most cases of biliary cirrhosis result from congenital abnormalities of the bile ducts (biliary atresia, choledochal cyst), tumors of the bile duct, Caroli disease, PFIC, primary sclerosing cholangitis, paucity of the intrahepatic bile ducts, and cystic fibrosis.

Occasionally, cirrhosis may follow a hypersensitivity reaction to certain drugs such as phenytoin. Parasites (Opisthorchis sinensis, Fasciola, and Ascaris) may be causative in children living in endemic areas.

**Clinical Findings**

**A. Symptoms and Signs**

Malaise, loss of appetite, failure to thrive, and nausea are frequent complaints, especially in anicteric varieties. Easy bruising may be reported. Jaundice may or may not be present. The first indication of underlying liver disease may be ascites, gastrointestinal hemorrhage, or hepatic encephalopathy. Variable hepatosplenomegaly, spider angiomas, warm skin, palmar erythema, or digital clubbing may be present. A small, shrunken liver may present. Most often, the liver is enlarged slightly, especially in the subxiphoid region, where it has a firm to hard quality and an irregular edge. Ascites may be detected as shifting dullness or a fluid wave. Gynecomastia may be noted in males. Digital clubbing occurs in 10–15% of cases. Pretibial edema often occurs, reflecting underlying hypoproteinemia. In adolescent girls, irregularities of menstruation and amenorrhea may be early complaints.

In biliary cirrhosis, patients often have jaundice, dark urine, pruritus, hepatomegaly, and sometimes xanthomas in addition to the previously mentioned clinical findings. Malnutrition and failure to thrive due to steatorrhea may be more apparent in this form of cirrhosis.

**B. Laboratory Findings**

Mild abnormalities of aminotransferases (AST, ALT) are often present, with a decreased level of albumin and a variable increase in the level of γ-globulins. Prothrombin time is prolonged and may be unresponsive to vitamin K administration. Burr and target red cells may be noted on the peripheral blood smear. Anemia, thrombocytopenia, and leukopenia are present if hypersplenism exists. However, cirrhosis may be present despite normal blood tests.

In biliary cirrhosis, elevated conjugated bilirubin, bile acids, GGT, alkaline phosphatase, and cholesterol are common.

**C. Imaging**

Hepatic ultrasound or CT examination may demonstrate abnormal hepatic texture and nodules. In biliary cirrhosis,
abnormalities of the biliary tree may be apparent by ultrasonography, CT, hepatobiliary scintigraphy, or cholangiography.

D. Pathologic Findings

Liver biopsy findings of regenerating nodules and surrounding fibrosis are hallmarks of cirrhosis. Pathologic features of biliary cirrhosis also include canalicular and hepatocyte cholestasis, as well as plugging of bile ducts. The interlobular bile ducts may be increased or decreased, depending on the cause and the stage of the disease process.

Complications & Treatment

Major complications of cirrhosis in childhood include progressive nutritional disturbances, hormonal disturbances, and the evolution of portal hypertension and its complications. Hepatocellular carcinoma occurs with increased frequency in the cirrhotic liver, especially in patients with the chronic form of hereditary tyrosinemia or after long-standing HBV or HCV disease. At present, there is no proven medical treatment for cirrhosis, but whenever a treatable condition is identified (eg, Wilson disease, galactosemia, congenital fructose intolerance, autoimmune hepatitis) or an offending agent eliminated (HBV, HCV, drugs, toxins), disease progression can be altered; occasionally regression of fibrosis has been noted. Children with cirrhosis should receive the hepatitis A and B vaccines, and they should be monitored for the development of hepatocellular carcinoma with serial serum α-fetoprotein determinations and abdominal ultrasound for hepatic nodules. Liver transplantation may be appropriate in patients with cirrhosis whose disease is continuing to progress, with evidence of worsening hepatic synthetic function, or in whom the complications of cirrhosis are no longer manageable.

Prognosis

Postnecrotic cirrhosis has an unpredictable course. Without transplantation, affected patients may die from liver failure within 10–15 years. Patients with a rising bilirubin, a vitamin K-resistant coagulopathy, or diuretic refractory ascites usually survive less than 1–2 years. The terminal event in some patients may be generalized hemorrhage, sepsis, or cardiorespiratory arrest. For patients with biliary cirrhosis, the prognosis is similar, except for those with surgically corrected lesions that result in regression or stabilization of the underlying liver condition. With liver transplantation, the long-term survival rate is 70–90%.

occur following the repair of an omphalocele or gastroschisis. Congenital vena caval bands, webs, a membrane, or stricture above the hepatic veins are sometimes causative. Hepatic vein thrombosis may be a complication of oral contraceptive medications. Underlying thrombotic conditions (deficiency of antithrombin III, protein C or S, or factor V Leiden; antiphospholipid antibodies; or mutations of the prothrombin gene) should be evaluated.

C. Intrahepatic Portal Hypertension

1. Cirrhosis—See previous section.

2. Veno-occlusive disease (acute stage)—This entity now occurs most frequently in bone marrow transplant recipients. It may also develop after chemotherapy for acute leukemia, particularly with thioguanine. Additional causes include the ingestion of pyrrolizidine alkaloids (“bush tea”) or other herbal teas, and a familial form of the disease occurring in congenital immunodeficiency states. The acute form of the disease generally occurs in the first month after bone marrow transplantation and is heralded by the triad of weight gain (ascites), tender hepatomegaly, and jaundice.

3. Congenital hepatic fibrosis—This is a rare autosomal recessive cause of intrahepatic presinusoidal portal hypertension (see Table 21–8). Liver biopsy is generally diagnostic, demonstrating Meyenburg complexes. On angiography, the intrahepatic branches of the portal vein may be duplicated. Autosomal recessive polycystic kidney disease is often associated with the hepatic lesion; therefore, renal ultrasonography and urography should be routinely performed.

4. Other rare causes—Hepatoportal sclerosis (idiopathic portal hypertension, noncirrhotic portal fibrosis), noncirrhotic nodular transformation of the liver, and schistosomal hepatic fibrosis are also rare causes of intrahepatic presinusoidal portal hypertension.

Clinical Findings

A. Symptoms and Signs

For prehepatic portal hypertension, splenomegaly in an otherwise well child is the most constant physical sign. Recurrent episodes of abdominal distention resulting from ascites may be noted. The usual presenting symptoms are hematemesis and melena.

The presence of prehepatic portal hypertension is suggested by the following: (1) an episode of severe infection in the newborn period or early infancy—especially omphalitis, sepsis, gastroenteritis, severe dehydration, or prolonged or difficult umbilical vein catheterizations; (2) no previous evidence of liver disease; (3) a history of well-being prior to onset or recognition of symptoms; and (4) normal liver size and tests with splenomegaly.

Most patients with suprahepatic portal hypertension present with abdominal pain, tender hepatomegaly of acute onset, and abdominal enlargement caused by ascites. Jaundice is present in only 25% of patients. Vomiting, hematemesis, and diarrhea are less common. Cutaneous signs of chronic liver disease are often absent, as the obstruction is usually acute. Distended superficial veins on the back and the anterior abdomen, along with dependent edema, are seen when inferior vena cava obstruction affects hepatic vein outflow. Absence of hepatojugular reflux (jugular distention when pressure is applied to the liver) is a helpful clinical sign.

The symptoms and signs of intrahepatic portal hypertension are generally those of cirrhosis (see earlier section on Cirrhosis).

B. Laboratory Findings and Imaging

Most other common causes of splenomegaly or hepatosplenomegaly may be excluded by appropriate laboratory tests. Cultures, EBV titers, hepatitis serologies, blood smear examination, bone marrow studies, and LFTs may be necessary. In prehepatic portal hypertension, LFTs are generally normal. In Budd-Chiari syndrome and veno-occlusive disease, mild to moderate hyperbilirubinemia with modest elevations of aminotransferases and prothrombin time are often present. Significant early increases in fibrinolytic parameters (especially plasminogen activator inhibitor 1) have been reported in veno-occlusive disease. Hypersplenism with mild leukopenia and thrombocytopenia is often present. Upper endoscopy may reveal varices in symptomatic patients.

Doppler-assisted ultrasound scanning of the liver, portal vein, splenic vein, inferior vena cava, and hepatic veins may assist in defining the vascular anatomy. In prehepatic portal hypertension, abnormalities of the portal or splenic vein may be apparent, whereas the hepatic veins are normal. When noncirrhotic portal hypertension is suspected, angiography often is diagnostic. Selective arteriography of the superior mesenteric artery or MRI is recommended prior to surgical shunting to determine the patency of the superior mesenteric vein.

For suprahepatic portal hypertension, an inferior venacavogram using catheters from above or below the suspected obstruction may reveal an intrinsic filling defect, an infiltrating tumor, or extrinsic compression of the inferior vena cava by an adjacent lesion. A large caudate lobe of the liver suggests Budd-Chiari syndrome. Care must be taken in interpreting extrinsic pressure defects of the subdiaphragmatic inferior vena cava if ascites is significant.

Simultaneous wedged hepatic vein pressure and hepatic venography are useful to demonstrate obstruction to major hepatic vein ostia and smaller vessels. In the absence of obstruction, reflux across the sinusoids into the portal vein branches can be accomplished. Pressures should also be taken from the right heart and supradiaphragmatic portion of the inferior vena cava to eliminate constrictive pericarditis and pulmonary hypertension from the differential diagnosis.
Differential Diagnosis

All causes of splenomegaly must be included in the differential diagnosis. The most common ones are infections, immune thrombocytopenic purpura, blood dyscrasias, lipidosis, reticuloendotheliosis, cirrhosis of the liver, and cysts or hemangiomas of the spleen. When hematomesis or melena occurs, other causes of gastrointestinal bleeding are possible, such as gastric or duodenal ulcers, tumors, duplications, and inflammatory bowel disease.

Because ascites is almost always present in suprahepatic portal hypertension, cirrhosis resulting from any cause must be excluded. Other suprahepatic (cardiac, pulmonary) causes of portal hypertension must also be ruled out. Although ascites may occur in prehepatic portal hypertension, it is uncommon.

Complications

The major manifestation and complication of portal hypertension is bleeding from esophageal varices. Fatal exsanguination is uncommon, but hypovolemic shock or resulting anemia may require prompt treatment. Hypersplenism with leukopenia and thrombocytopenia occurs, but seldom causes major symptoms. Rupture of the enlarged spleen secondary to trauma is always a threat. Retroperitoneal edema has been reported (Clatworthy sign).

Without treatment, complete and persistent hepatic vein obstruction leads to liver failure, coma, and death. A non-portal type of cirrhosis may develop in the chronic form of hepatic veno-occlusive disease in which small- and medium-sized hepatic veins are affected. Death from renal failure may occur in rare cases of congenital hepatic fibrosis.

Treatment

Definitive treatment of noncirrhotic portal hypertension is generally lacking. Aggressive medical treatment of the complications of prehepatic portal hypertension is generally quite effective. The early experience with surgical portosystemic shunts was unfavorable. Recently, several centers have reported excellent results with either portosystemic shunt or the mesorex (mesenterico–left portal bypass) shunt. When possible, the mesorex shunt is the preferred technique. Veno-occlusive disease may be prevented somewhat by the prophylactic use of UDCA or defibrotide prior to conditioning for bone marrow transplantation. Treatment with defibrotide and withdrawal of the suspected offending agent, if possible, may increase the chance of recovery. Transjugular intrahepatic portosystemic shunts have been successful bridging to recovery in veno-occlusive disease. For suprahepatic portal hypertension, efforts should be directed at correcting the underlying cause, if possible. Either surgical or angiographic relief of obstruction should be attempted if a defined obstruction of the vessels is apparent. Liver transplantation, if not contraindicated, should be considered early if direct correction is not possible. In most cases, management of portal hypertension is directed at management of the complications (Table 21–7).

Prognosis

For prehepatic portal hypertension, the prognosis depends on the site of the block, the effectiveness of variceal eradication, the availability of suitable vessels for shunting procedures, and the experience of the surgeon. In patients treated by medical means, bleeding episodes seem to diminish with adolescence.

| Table 21–7. Treatment of complications of portal hypertension. |
|---|---|---|
| **Complication** | **Diagnosis** | **Treatment** |
| Bleeding esophageal varices | Endoscopic verification of variceal bleeding. | Endosclerosis or variceal band ligation. Octreotide, 30 mcg/m²/h intravenously. Pediatric Sengstaken-Blakemore tube. Surgical variceal ligation, selective venous embolization, surgical portosystemic shunt, TIPS, OLT. Propranolol may be useful to prevent recurrent bleeding. |
| Ascites | Clinical examination (fluid wave, shifting dullness), abdominal ultrasound. | Sodium restriction (1-2 mEq/kg/d), spironolactone (3-5 mg/kg/d), furosemide (1-2 mg/kg/d), intravenous albumin (0.5-1 g/kg per dose), paracentesis, peritoneovenous (LeVeen) shunt, TIPS, surgical portosystemic shunt, OLT.¹ |
| Hepatic encephalopathy | Abnormal neurologic examination, elevated plasma ammonia. | Protein restriction (0.5-1 g/kg/d), intravenous glucose (6-8 g/kg/min), neomycin (2-4 g/m² BSA PO in 4 doses), rifaximin (200 mg 3 times a day in children > 12 y), lactulose (1 mL/kg per dose [up to 30 mL] every 4-6 h PO), plasmapheresis, hemodialysis, OLT.² |
| Hypersplenism | Low WBC count, platelets, and/or hemoglobin. Splenomegaly. | No intervention, partial splenic embolization, TIPS, surgical portosystemic shunt, OLT. Splenectomy may worsen variceal bleeding. |

¹In order of sequential management.

²BSA, body surface area; OLT, orthotopic liver transplantation; TIPS, transjugular intrahepatic portosystemic shunt; WBC, white blood cell.
The prognosis in patients treated by medical and supportive therapy may be better than in the surgically treated group, especially when surgery is performed at an early age, although no comparative study has been done. Portacaval encephalopathy is unusual after shunting except when protein intake is excessive, but neurologic outcome may be better in patients who receive a mesorex shunt when compared with medical management alone.

The mortality rate of hepatic vein obstruction is very high (95%). In veno-occlusive disease, the prognosis is better, with complete recovery possible in 50% of acute forms and 5–10% of subacute forms.

**BILIARY TRACT DISEASE**

1. **Cholelithiasis**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Episodic right upper quadrant abdominal pain.
- Elevated bilirubin, alkaline phosphatase, and GGT.
- Stones or sludge seen on abdominal ultrasound.

**General Considerations**

Gallstones may develop at all ages in the pediatric population and in utero. Gallstones may be divided into cholesterol stones (which contain more than 50% cholesterol) and pigment (black [sterile bile] and brown [infected bile]) stones. Pigment stones predominate in the first decade of life, while cholesterol stones account for up to 90% of gallstones in adolescence. For some patients, gallbladder dysfunction is associated with biliary sludge formation, which may evolve into “sludge balls” or tumefaction bile and then into gallstones. The process is reversible in many patients.

**Clinical Findings**

**A. History**

Most symptomatic gallstones are associated with acute or recurrent episodes of moderate to severe, sharp right upper quadrant or epigastric pain. The pain may radiate subcostally or to the right shoulder. On rare occasions, the presentation may include a history of jaundice, back pain, or generalized abdominal discomfort, when it is associated with pancreatitis, suggesting stone impaction in the common duct or ampulla hepatopancreatica. Nausea and vomiting may occur during attacks. Pain episodes often occur postprandially, especially after ingestion of fatty foods. The groups at risk for gallstones include patients with known or suspected hemolytic disease; females; teenagers with prior pregnancy; obese individuals; individuals with rapid weight loss; children with portal vein thrombosis; certain racial or ethnic groups, particularly Native Americans (Pima Indians) and Hispanics; infants and children with ileal disease (Crohn disease) or prior ileal resection; patients with cystic fibrosis or Wilson disease; and infants on prolonged parenteral hyperalimentation. Other, less certain risk factors include a positive family history, use of birth control pills, and diabetes mellitus.

**B. Symptoms and Signs**

During acute episodes of pain, tenderness is present in the right upper quadrant or epigastrium, with a positive inspiratory arrest (Murphy sign), usually without peritoneal signs. While rarely present, scleral icterus is helpful. Evidence of underlying hemolytic disease in addition to icterus may include pallor (anemia), splenomegaly, tachycardia, and high-output cardiac murmur. Fever is unusual in uncomplicated cases.

**C. Laboratory Findings**

Laboratory tests are usually normal unless calculi have lodged in the extrahepatic biliary system, in which case the serum bilirubin and GGT (or alkaline phosphatase) may be elevated. Amylase and lipase levels may be increased if stone obstruction occurs at the ampulla hepatopancreatica.

**D. Imaging**

Ultrasound evaluation is the best imaging technique, showing abnormal intraluminal contents (stones, sludge) as well as anatomic alterations of the gallbladder or dilation of the biliary ductal system. The presence of an anechoic acoustic shadow differentiates calculi from intraluminal sludge or sludge balls.
Ceftriaxone may cause similar findings. Plain abdominal radiographs will show calculi with a high calcium content in the region of the gallbladder in up to 15% of patients. Lack of visualization of the gallbladder with hepatobiliary scintigraphy suggests chronic cholecystitis. In selected cases, ERCP, MRCP, or endoscopic ultrasound may be helpful in defining subtle abnormalities of the bile ducts and locating intraductal stones.

**Differential Diagnosis**

Other abnormal conditions of the biliary system with similar presentation are summarized in Table 21–8. Liver disease (hepatitis, abscess, or tumor) can cause similar symptoms or signs. Peptic disease, reflux esophagitis, paraesophageal hiatal hernia, cardiac disease, and pneumomediastinum must be considered when the pain is epigastric or substernal in location. Renal or pancreatic disease is a possible explanation if the pain is localized to the right flank or mid back. Subcapsular or supracapsular lesions of the liver (abscess, tumor, or hematoma) or right lower lobe infiltrate may also be a cause of nontraumatic right shoulder pain.

**Complications**

Major problems are related to stone impaction in either the cystic or common duct and may lead to stricture formation or perforation. Acute distention and subsequent perforation of the gallbladder may occur when gallstones cause obstruction of the cystic duct. Stones impacted at the level of the ampulla hepatopancreatica often cause gallstone pancreatitis.

**Treatment**

Symptomatic cholelithiasis is treated by laparoscopic cholecystectomy or open cholecystectomy in selected cases. Intraoperative cholangiography via the cystic duct is recommended so that the physician can be certain the biliary system is free of retained stones. Calculi in the extrahepatic bile ducts may be removed at ERCP.

Gallstones developing in premature infants on parenteral nutrition can be followed by ultrasound examination. Most of the infants are asymptomatic, and the stones will resolve in 3–36 months. Gallstone dissolution using cholelitholytics (UCDA) or mechanical means (lithotripsy) has not been approved for use in children. Asymptomatic gallstones do not usually require treatment, as less than 20% will eventually cause problems.

**Prognosis**

The prognosis is excellent in uncomplicated cases that come to standard cholecystectomy.

---

**2. Primary Sclerosing Cholangitis**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Pruritus and jaundice.
- Elevated GGT.
- Associated with inflammatory bowel disease.
- Abnormal ERCP or MRCP.

**General Considerations**

Primary sclerosing cholangitis (PSC) is a progressive liver disease of unknown cause, characterized by chronic inflammation and fibrosis of the intrahepatic or extrahepatic bile ducts (or both), with eventual obliteration of peripheral bile ducts, cholangiographic evidence of strictures, and dilation of all or parts of the biliary tree. PSC is more common in males with inflammatory bowel disease, particularly ulcerative colitis. It can also be seen with histiocytosis X, sicca syndromes, congenital and acquired immunodeficiency syndromes, and cystic fibrosis.

**Clinical Findings**

**A. Symptoms and Signs**

PSC often has an insidious onset. Clinical symptoms may include abdominal pain, fatigue, pruritus, and jaundice. Acholic stools and steatorrhea can occur. Physical findings include hepatomegaly, splenomegaly, and jaundice.

**B. Laboratory Findings**

The earliest finding may be asymptomatic elevation of the GGT. Subsequent laboratory abnormalities include elevated levels of alkaline phosphatase and bile acids. Later, cholestatic jaundice and elevated AST and ALT may occur. Patients with associated inflammatory bowel disease often test positive for perinuclear antineutrophil cytoplasmic antibodies. Other markers of autoimmune liver disease (ANA and anti–smooth muscle antibodies [ASMA]) are often found but are not specific for PSC. Sclerosing cholangitis due to cryptosporidia is common in immunodeficiency syndromes.

**C. Imaging**

Ultrasound may show dilated intrahepatic bile ducts behind strictures. MRCP is now the diagnostic study of choice, demonstrating irregularities of the biliary tree. ERCP may be more sensitive for the diagnosis of irregularities of the intrahepatic biliary tree.

**Prognosis**

- Excellent with resolution of underlying condition. Consider cystic duct obstruction if disorder fails to resolve.
- Depends on anatomic type of cyst, associated condition, and success of surgery. Liver transplantation required in some.
- Good with early diagnosis and treatment.
- Poor, with gradual deterioration of liver function. Multiple surgical drainage procedures expected. Liver transplantation should improve long-term prognosis.
- Good in absence of serious renal involvement and with control of portal hypertension. Slightly increased risk of cholangiocarcinoma.
- Good short-term outcome in well-selected patients.

AST, aspartate aminotransferase; CCK, cholecystokinin; CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; GGT, glutamyl transpeptidase; LFT, liver function tests; MRCP, magnetic resonance cholangiopancreatography; RUQ, right upper quadrant; WBC, white blood count.
**Differential Diagnosis**

The differential diagnosis includes infectious hepatitis, secondary cholangitis, autoimmune hepatitis, metabolic liver disease, cystic fibrosis, choledochal cyst, or other anomalies of the biliary tree, including Caroli disease and congenital hepatic fibrosis (see Table 21–8).

**Complications**

Complications include secondary bacterial cholangitis, pancreatitis, biliary fibrosis, and cirrhosis. Progression to liver failure is common, and the risk of cholangiocarcinoma is higher in PSC.

**Treatment**

No completely effective treatment is available. Patients with early disease may benefit from high-dose UCDA (25–30 mg/kg/d). Patients with autoimmune markers may benefit from treatment with corticosteroids and azathioprine. Antibiotic treatment of cholangitis and dilation and stenting of dominant bile duct strictures can reduce symptoms.

**Prognosis**

The majority of patients will eventually require liver transplantation, and PSC is the fifth leading indication for liver transplantation in the United States. The median duration from the time of diagnosis to end-stage liver disease is 12–15 years.

**General Considerations**

Pyogenic liver abscesses are often caused by intestinal bacteria seeded via the portal vein from infected viscera and occasionally from ascending cholangitis or gangrenous cholecystitis. Blood cultures are positive in up to 60% of patients. The resulting lesion tends to be solitary and located in the right hepatic lobe. Bacterial seeding may also occur from infected burns, pyoderma, and osteomyelitis. Unusual causes include omphalitis, subacute infective endocarditis, pyelonephritis, Crohn disease, and perinephric abscess. In immunocompromised patients, S aureus, gram-negative organisms, and fungi may seed the liver from the arterial system. Multiple pyogenic liver abscesses are associated with severe sepsis. Children receiving anti-inflammatory and immunosuppressive agents and children with defects in white blood cell function (chronic granulomatous disease) are prone to pyogenic hepatic abscesses, especially those caused by S aureus.

Amoebic liver abscess is rare in children. An increased risk is associated with travel in areas of endemic infection (Mexico, Southeast Asia) within 5 months of presentation. Entamoeba histolytica invasion occurs via the large bowel, although a history of diarrhea (colitis-like picture) is not always obtained.

**Clinical Findings**

With pyogenic liver abscess, nonspecific complaints of fever, chills, malaise, and abdominal pain are frequent. Weight loss

---

**PYOGENIC & AMEBIC LIVER ABSCESS**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Fever and painful enlarged liver.
- Ultrasound of liver demonstrating an abscess.
- Positive serum ameba antibody or positive bacterial culture of abscess fluid.

---

3. Other Biliary Tract Disorders

For a schematic representation of the various types of choledochal cysts, see Figure 21–1. For summary information on acute hydrops, choledochal cyst, acalculous cholecystitis, Caroli disease, biliary dyskinesia, and congenital hepatic fibrosis, see Table 21–8.
is very common, especially in delayed diagnosis. A few patients have shaking chills and jaundice. The dominant complaint is a constant dull pain over an enlarged liver that is tender to palpation. An elevated hemidiaphragm with reduced or absent respiratory excursion may be demonstrated on physical examination and confirmed by fluoroscopy. Laboratory studies show leukocytosis and, at times, anemia. LFTs may be normal or reveal mild elevation of transaminases and alkaline phosphatase. Fever and abdominal pain are the two most common symptoms of amebic liver abscess. Abdominal tenderness and hepatomegaly are present in over 50%. Early in the course, LFTs may suggest mild hepatitis. An occasional prodrome may include cough, dyspnea, and shoulder pain when rupture of the abscess into the right chest occurs. Consolidation of the right lower lobe is common (10–30% of patients).

Ultrasound liver scan is the most useful diagnostic aid in evaluating pyogenic and amebic abscesses, detecting lesions as small as 1–2 cm. MRI, CT, or nuclear scanning with gallium or technetium sulfur colloid may be useful in differentiating tumor or hydatid cyst.

The distinction between pyogenic and amebic abscesses is best made by indirect hemagglutination test for specific antibody (which is positive in more than 95% of patients with amebic liver disease) and the prompt clinical response of the latter to antiamebic therapy (metronidazole). Examination of material obtained by needle aspiration of the abscess using ultrasound guidance is often diagnostic.

Differential Diagnosis

Hepatitis, hepatoma, hydatid cyst, gallbladder disease, or biliary tract infections can mimic liver abscess. Subphrenic abscesses, empyema, and pneumonia may give a similar picture. Inflammatory disease of the intestines or of the biliary system may be complicated by liver abscess.

Complications

Spontaneous rupture of the abscess may occur with extension of infection into the subphrenic space, thorax, peritoneal cavity, and, occasionally, the pericardium. Bronchopleural fistula with large sputum production and hemoptysis can develop in severe cases. Simultaneously, the amebic liver abscess may be secondarily infected with bacteria (in 10–20% of patients). Metastatic hematogenous spread to the lungs and the brain has been reported.

Treatment

Ultrasound- or CT-guided percutaneous needle aspiration for aerobic and anaerobic culture with simultaneous placement of a catheter for drainage, combined with appropriate antibiotic therapy, is the treatment of choice for solitary pyogenic liver abscess. Multiple liver abscesses may also be treated successfully by this method. Surgical intervention may be indicated if rupture occurs outside the capsule of the liver or if enterohepatic fistulae are suspected.

Amebic abscesses in uncomplicated cases should be treated promptly with oral metronidazole, 35–50 mg/kg/d, in three divided doses for 10 days. Intravenous metronidazole can be used for patients unable to take oral medication. Failure to improve after 72 hours of drug therapy suggests superimposed bacterial infection or an incorrect diagnosis. At this point, needle aspiration or surgical drainage is indicated. Once oral feedings can be tolerated, a luminal amebicide such as iodoquinol should be initiated. Resolution of the abscess cavity occurs over 3–6 months.

Prognosis

An unrecognized and untreated pyogenic liver abscess is universally fatal. With drainage and antibiotics, the cure rate is about 90%. Most amebic abscesses are cured with conservative medical management; the mortality rate is less than 3%. If extrahepatic complications occur (empyema, bronchopleural fistula, or pericardial complications), 10–15% of patients will succumb.

HEPATOMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Abdominal enlargement and pain, weight loss, anemia.
- Hepatomegaly with or without a definable mass.
- Mass lesion on imaging studies.
- Laparotomy and tissue biopsy.

General Considerations

Primary epithelial neoplasms of the liver represent 0.2–5.8% of all malignant conditions in children. After Wilms tumor and neuroblastoma, hepatomas are the third most common intra-abdominal cancer. The incidence is higher in Southeast Asia, where childhood cirrhosis is more common. There are two basic morphologic types with certain clinical and prognostic differences. Hepatoblastoma predominates in male infants and children and accounts for 79% of liver cancer in children, with most cases appearing before age 5 years. There
is an increased risk of hepatoblastoma in Beckwith-Wiedemann syndrome, hemihypertrrophy, familial adenomatosis polyposis coli, and in premature or low-birth-weight infants. Most lesions are found in the right lobe of the liver. Pathologic differentiation from hepatocellular carcinoma, the other major malignant tumor of the liver, may be difficult. Hepatocellular carcinoma occurs more frequently after age 3 years, carries a worse prognosis than hepatoblastoma, and causes more abdominal discomfort.

Patients with chronic HBV or HCV infection, cirrhosis, glycogen storage disease type I, tyrosinemia, or α₁-antitrypsin deficiency have an increased risk for hepatocellular carcinoma. The late development of hepatocellular carcinoma in patients receiving androgens for treatment of Fanconi syndrome and aplastic anemia must also be kept in mind. The use of anabolic steroids by body-conscious adolescents poses a risk of hepatic neoplasia.

An interesting aspect of primary epithelial neoplasms of the liver has been the increased incidence of associated anomalies and endocrine abnormalities. Virilization has been reported as a consequence of gonadotropin activity of the tumor. Feminization with bilateral gynecomastia may occur in association with high estradiol levels in the blood, the latter a consequence of increased aromatization of circulating androgens by the liver. Leydig cell hyperplasia without the latter a consequence of increased aromatization of circulating androgens by the liver. Hemihypertrophy, congenital absence of the kidney, macroglossia, and Meckel diverticulum have been found in association with hepatocellular carcinoma.

C. Imaging

Ultrasoundography, CT, and MRI are useful for diagnosis, staging, and to follow tumor response to therapy. A scintigraphic study of bone and lung and selective angiography are generally part of the preoperative workup to evaluate metastatic disease.

Differential Diagnosis

In the absence of a palpable mass, the differential diagnosis is that of hepatomegaly with or without anemia or jaundice. Hematologic and nutritional conditions should be ruled out, as well as HBV and HCV infection, α₁-antitrypsin deficiency disease, lipoid storage diseases, histiocytosis X, glycogen storage disease, tyrosinemia, congenital hepatic fibrosis, cysts, adenoma, focal nodular hyperplasia, inflammatory pseudotumor, and hemangiomas. If fever is present, hepatic abscess (pyogenic or amebic) must be considered. Veno-occlusive disease and hepatic vein thrombosis are rare possibilities. Tumors in the left lobe may be mistaken for pancreatic pseudocysts.

Complications

Progressive enlargement of the tumor, abdominal discomfort, ascites, respiratory difficulty, and widespread metastases (especially to the lungs and the abdominal lymph nodes) are the rule. Rupture of the neoplastic liver and intraperitoneal hemorrhage have been reported. Progressive anemia and emaciation predispose the patient to an early septic death.

Treatment

An aggressive surgical approach has resulted in the only reports of long-term survival. Complete resection of the lesion offers the only chance for cure. It appears that every isolated lung metastasis should also be surgically resected. Radiotherapy and chemotherapy have been disappointing in the treatment of primary liver neoplasms, although they may be used for initial cytoreduction of tumors found to be unresectable at the time of primary surgery (see Chapter 29 for additional discussion). Second-look celiotomy has, in some cases, allowed resection of the tumor, resulting in a reduced mortality rate. Liver transplantation can be an option in hepatoblastoma with 85% 10-year survival in patients with unresectable disease limited to the liver. For hepatocellular carcinoma, the survival rate is poor due to the typically advanced stage at diagnosis. The survival rate may be better for those patients in whom the tumor is incidental to another disorder (tyrosinemia, biliary atresia, cirrhosis). In HBV-endemic areas, childhood HBV vaccination has reduced the incidence of hepatocellular carcinoma.

Prognosis

If the tumor is completely removed the survival rate is 90% for hepatoblastoma and 33% for hepatocellular carcinoma. If metastases are present, survival is reduced to 40% for hepatoblastoma.
LIVER TRANSPLANTATION

Orthotopic liver transplantation is indicated in children with end-stage liver disease, acute fulminant hepatic failure, or complications from metabolic liver disorders. Recent advances in immunosuppression (eg, cyclosporine and tacrolimus, use of monoclonal antibodies against T cells, introduction of mycophenolate mofetil and sirolimus), better candidate selection, improvements in surgical techniques, antiviral medications, and experience in postoperative management have contributed to improved results.

The major indications for childhood transplantation are:

1. A failed Kasai operation or decompensated cirrhosis caused by biliary atresia.
2. α1-Antitrypsin deficiency causing end-stage liver disease.
3. Posthepatitic (autoimmune chronic hepatitis, hepatitis B or C disease) cirrhosis.
4. Tyrosinemia.
7. Acute liver failure when recovery is unlikely.
8. Primary sclerosing cholangitis.
10. Cases in which the consequences of chronic cholestasis severely impair the patient’s quality of life (eg, Alagille syndrome).

Children should be referred early for evaluation because the limiting factor for success is the small donor pool. Paedradn adult livers, organs from living related donors, and split adult donor livers have expanded the donor pool, in addition to whole pediatric donor organs. Ten percent of recipients require retransplantation. In general, 80–90% of children survive at least 2–5 years after transplantation, with long-term survival expected to be comparable. Lifetime immunosuppression therapy, using combinations of tacrolimus, cyclosporine, prednisone, azathioprine, mycophenolate mofetil, or sirolimus, with its incumbent risks, is generally necessary to prevent rejection. Several studies have examined immunosuppression withdrawal, which can occasionally be performed successfully; however, criteria for which patients can survive off of immunosuppression have not been determined. The minimal amount of immunosuppression that will prevent allograft rejection should be chosen. The overall quality of life for children with a transplanted liver appears to be excellent. There is an increased risk (up to 25%) of renal dysfunction. The lifelong risk of EBV-induced lymphoproliferative disease is approximately 5% and is related to age, EBV exposure status at time of transplantation, and intensity of immunosuppression. Various protocols are being tested for prevention and treatment of lymphoproliferative disease.

PANCREATIC DISORDERS

ACUTE PANCREATITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Epigastric abdominal pain radiating to the back.
- Nausea and vomiting.
- Elevated serum amylase and lipase.
- Evidence of pancreatic inflammation by CT or ultrasound.

General Considerations

Most cases of acute pancreatitis are the result of drugs, viral infections, systemic diseases, abdominal trauma, or obstruction of pancreatic flow. More than 20% are idiopathic. Causes of pancreatic obstruction include stones, choledochal cyst, tumors of the duodenum, pancreas divisum, and ascariasis. Acute pancreatitis has been seen following treatment with sulfasalazine, thiazides, valproic acid, azathioprine, mercaptopurine, asparaginase, antiretroviral drugs (especially didanosine), high-dose corticosteroids, and other drugs. It may also occur in cystic fibrosis, systemic lupus erythematosus, α1-antitrypsin deficiency, diabetes mellitus, Crohn disease, ganciogen storage disease type I, hyperlipidemia types I and V, hyperparathyroidism, Henoch-Schönlein purpura, Reye syndrome, organic acidopathies, Kawasaki disease, or chronic...
renal failure; during rapid refeeding in cases of malnutrition; following spinal fusion surgery; and in familial cases. Alcohol-induced pancreatitis should be considered in the teenage patient.

**Clinical Findings**

**A. Symptoms and Signs**

An acute onset of persistent (hours to days), moderate to severe upper abdominal and midabdominal pain occasionally referred to the back, and vomiting, is the common presenting picture. The abdomen is tender, but not rigid, and bowel sounds are diminished, suggesting peritoneal irritation. Abdominal distention is common in infants and younger children. Jaundice is unusual. Ascites may be noted, and a left-sided pleural effusion is present in some patients. Periumbilical and flank bruising indicate hemorrhagic pancreatitis.

**B. Laboratory Findings**

Leukocytosis and an elevated serum amylase (more than three times normal) should be expected early, except in infants younger than 6 months who may have hypoamylasemia. Serum lipase is elevated and persists longer than serum amylase. The immunoreactive trypsinogen may also be elevated. Pancreatic amylase isoenzyme determination can help differentiate nonpancreatic causes (eg, salivary, intestinal, or tubo-ovarian) of serum amylase elevation. Hyperglycemia (serum glucose > 300 mg/dL), hypocalcemia, falling hematocrit, rising blood urea nitrogen, hypoxemia, and acidosis may all occur in severe cases and imply a poor prognosis.

**C. Imaging**

Plain radiographic films of the abdomen may show a localized ileus (sentinel loop). Ultrasonography shows decreased echodensity of the gland in comparison with the left lobe of the liver. Pseudocyst formation can occasionally be seen early in the course. CT scanning is better for detecting pancreatic phlegmon, or abscess formation. ERCP or MRCP may be useful in confirming patency of the main pancreatic duct in cases of abdominal trauma; in recurrent acute pancreatitis; or in revealing stones, ductal strictures, and pancreas divisum.

**Differential Diagnosis**

Other causes of acute upper abdominal pain include lesions of the stomach, duodenum, liver, and biliary system; acute gastroenteritis or atypical appendicitis; pneumonia; volvulus; intussusception; and nonaccidental trauma.

**Complications**

Complications early in the disease include shock, fluid and electrolyte disturbances, ileus, acute respiratory distress syndrome, and hypocalcemia. Hypervolemia is seen between the third and fifth day, at which time renal tubular necrosis may occur. The gastrointestinal, neurologic, musculoskeletal, hepatobiliary, dermatologic, and hematologic systems may also be involved.

Later, 5–20% of patients develop a pseudocyst heralded by recurrence of abdominal pain and rise in the serum amylase. Up to 60–70% of pseudocysts resolve spontaneously. Infection, hemorrhage, rupture, or fistulization may occur. Phlegmon formation is common and may extend from the gland into the retroperitoneum or into the lesser sac. Most regress, but some require drainage. Infection in this inflammatory mass may occur. Pancreatic abscess formation, which is rare (3–5%), develops 2–3 weeks after the initial insult. Fever, leukocytosis, and pain suggest this complication; diagnosis is made by ultrasound or CT scanning. Chronic pancreatitis, exocrine or endocrine pancreatic insufficiency, and pancreatic lithiasis are rare sequelae of acute pancreatitis.

**Treatment**

Medical management includes careful attention to fluids, electrolytes, and respiratory status. Gastric decompression may be helpful if there is significant vomiting. Pain should be controlled with opioids. Acid suppression may be helpful. Nutrition is provided by the parenteral or enteral (jejunal) route. Broad-spectrum antibiotic coverage is useful only in necrotizing pancreatitis. Drugs known to produce acute pancreatitis should be discontinued. Surgical treatment is reserved for traumatic disruption of the gland, intraductal stone, other anatomic obstructive lesions, and unresolved or infected pseudocysts or abscesses. Early endoscopic decompression of the biliary system reduces the morbidity associated with pancreatitis caused by obstruction of the common bile duct.

**Prognosis**

In the pediatric age group, the prognosis is surprisingly good with conservative management. The mortality rate is 5–10% in patients treated surgically and 1% in those treated only with medication. The morbidity rate is high with surgery as a result of fistula formation.

**CHRONIC PANCREATITIS**

Chronic pancreatitis is differentiated from acute pancreatitis in that the pancreas remains structurally or functionally abnormal after an attack.

The causes are multiple and can be divided into toxic-metabolic (eg, alcohol, chronic renal failure, hypercalcemia), idiopathic, genetic, autoimmune, recurrent and severe acute pancreatitis, and obstructive pancreatitis (eg, pancreas divisum, choledochoal cyst).
CHAPTE R 21

Clinical Findings

The diagnosis often is delayed by the nonspecificity of symptoms and the lack of persistent laboratory abnormalities.

A. Symptoms and Signs

There is usually a prolonged history of recurrent upper abdominal pain of variable severity. Radiation of the pain into the back is a frequent complaint. Fever and vomiting are not common. Steatorrhea and symptoms of diabetes may develop later in the course, and malnutrition secondary to failure of pancreatic exocrine secretions may also occur.

B. Laboratory Findings

Serum amylase and lipase levels are usually elevated during early acute attacks but are often normal later. Pancreatic insufficiency and reduced volume and bicarbonate response may be found during pancreatic stimulation testing or by determination of fecal pancreatic elastase 1. Mutations of the cationic trypsinogen gene, the pancreatic secretory trypsin inhibitor, and the cystic fibrosis transmembrane conductance regulator gene (CFTR) are associated with recurrent acute and chronic pancreatitis. Elevated blood glucose and glycohemoglobin levels and glycosuria frequently occur in protracted disease. Sweat chloride should be checked for cystic fibrosis and serum calcium for hyperparathyroidism.

C. Imaging

Radiographs of the abdomen may show pancreatic calcifications in up to 30% of patients. Ultrasound or CT examination demonstrates pancreatic enlargement, ductal dilation, and calculi in up to 80%. CT is the initial imaging procedure of choice. MRCP or ERCP can show ductal dilation, stones, strictures, or stenotic segments. Endoscopic ultrasound in the diagnosis and staging of chronic pancreatitis is being evaluated.

Differential Diagnosis

Other causes of recurrent abdominal pain must be considered. Specific causes of pancreatitis such as hyperparathyroidism; systemic lupus erythematosus; infectious disease; and ductal obstruction by tumors, stones, or helminths must be excluded by appropriate tests.

Complications

Disabling abdominal pain, steatorrhea, malnutrition, pancreatic pseudocysts, and diabetes are the most frequent long-term complications. Pancreatic carcinoma occurs more frequently in chronic pancreatitis, and in up to 40% of patients with hereditary pancreatitis by age 70.

Treatment

Medical management of acute attacks is indicated (see Acute Pancreatitis section). If ductal obstruction is strongly suspected, endoscopic therapy (balloon dilation, stenting, stone removal, or sphincterotomy) should be pursued. Relapses occur in most patients. Orally ingested nonenteric-coated pancreatic enzymes at mealtimes may reduce pain episodes in some patients. Antioxidant therapy is being investigated. Pseudocysts may be marsupialized to the surface or drained into the stomach or into a loop of jejunum if they fail to regress spontaneously. Experience in pediatric patients indicates that lateral pancreaticojejunostomy or the Frey procedure can reduce pain in patients with a dilated pancreatic duct and may prevent or delay progression of functional pancreatic impairment. Pancreatectomy and islet cell autotransplantation have been used in selected cases of chronic pancreatitis.

Prognosis

In the absence of a correctable lesion, the prognosis is not good. Disabling episodes of pain, pancreatic insufficiency, diabetes, and pancreatic cancer may ensue. Narcotic addiction and suicide are risks in teenagers with disabling disease.

Gastrointestinal & Hepatobiliary Manifestations of Cystic Fibrosis

Cystic fibrosis is a disease with protean manifestations. Although pulmonary and pancreatic involvement dominate the clinical picture for most patients (see Chapter 18), various other organs can be involved. Table 21-9 lists the important gastrointestinal, pancreatic, and hepatobiliary conditions that may affect patients with cystic fibrosis along with their clinical findings, incidence, most useful diagnostic studies, and preferred treatment.

Table 21–9. Gastrointestinal and hepatobiliary manifestations of cystic fibrosis.

(continued)
Pancreatic sufficiency (partial exocrine insufficiency)
- Occasional diarrhea, mild growth delay.
- Any age
- 72-h fecal fat evaluation, direct pancreatic function tests, fecal pancreatic elastase
- Increased serum lipase and amylase, pancreatic provocative test, MRCP, ERCP
- Glucose tolerance test and insulin levels
- Pancreatic enzyme replacement in selected patients. Fat-soluble vitamin supplements as indicated by biochemical evaluation.
- Addition of pancreatic enzymes to feeds, endoscopic removal of sludge or stones if present, endoscopic papillotomy.
- Diet, insulin, oral hypoglycemics.

Pancreatitis
- Recurrent abdominal pain, vomiting.
- 0.1
- Increased serum lipase and amylase, pancreatic provocative test, MRCP, ERCP
- Addition of pancreatic enzymes to feeds, endoscopic removal of sludge or stones if present, endoscopic papillotomy.
- Diet, insulin, oral hypoglycemics.

Diabetes
- Weight loss, polyuria, polydipsia.
- Older children through adolescence
- 5-7
- Glucose tolerance test and insulin levels
- Diet, insulin, oral hypoglycemics.

Liver
- Steatosis
  - Hepatomegaly.
  - Neonates and infants, but can be seen at all ages
  - 20-60
  - Liver biopsy
  - Improved nutrition, replacement of pancreatic enzymes, vitamins, and essential fatty acids.
- Focal biliary cirrhosis
  - Hepatomegaly.
  - Infants and older patients. Prevalence increases with age.
  - 10-70
  - Liver biopsy
  - As above. Ursodeoxycholic acid.
- Multilobular biliary cirrhosis
  - Hepatosplenomegaly, hematemesis from esophageal varices; hypersplenism, jaundice, ascites late in course.
  - School age through adolescence
  - 5-15
  - Liver biopsy, endoscopy
  - Improved nutrition, ursodeoxycholic acid, endosclerosis or band ligation of varices, or partial splenic embolization, liver transplantation.
- Neonatal jaundice
  - Cholestatic jaundice hepatomegaly; often seen with meconium ileus.
  - Neonates
  - 0.1-1
  - Sweat chloride test, liver biopsy
  - Nutritional support, special formula with medium-chain triglyceride-containing oil, pancreatic enzyme replacement, vitamin supplements.

Gallbladder
- Microgallbladder
  - None.
  - Congenital—present at any age
  - 30
  - Ultrasound or hepatobiliary scintigraphy
  - None needed.
- Cholelithiasis
  - Recurrent abdominal pain, rarely jaundice.
  - School age through adolescence
  - 1-10
  - Ultrasound
  - Surgery if symptomatic and low risk, trial of cholelitholytics in others.

Extrahepatic bile ducts
- Intrapancreatic compression (tumor)
  - Jaundice, hepatomegaly, abdominal pain.
  - Neonates, then older children through adolescence
  - Rare in neonates (< 0.1)
  - Ultrasound and hepatobiliary scintigraphy, MRCP
  - Surgery in neonates; ERCP in older patients or surgery.
- Extrapancreatic compression (tumor)
  - As above.
  - Older children to adults
  - Rare (< 1)
  - As above
  - Surgical biliary drainage procedure or ERCP.

Table 21-9. Gastrointestinal and hepatobiliary manifestations of cystic fibrosis. (Continued)
SYNDROMES WITH PANCREATIC EXOCRINE INSUFFICIENCY

Several syndromes are associated with exocrine pancreatic insufficiency. Clinically, patients present with a history of failure to thrive, diarrhea, fatty stools, and an absence of respiratory symptoms. Laboratory findings include a normal sweat chloride; low fecal pancreatic elastase 1; and low to absent pancreatic lipase, amylase, and trypsin levels on duodenal intubation. Each disorder has several associated clinical features that aid in the differential diagnosis. In Shwachman syndrome, pancreatic exocrine hypoplasia with widespread fatty replacement of the glandular acinar tissue is associated with neutropenia because of maturational arrest of the granulocyte series. Metaphyseal dysostosis and an elevated fetal hemoglobin level are common; immunoglobulin deficiency and hepatic dysfunction are also reported. CT examination of the pancreas demonstrates the widespread fatty replacement. Serum immunoreactive trypsinogen levels are extremely low.

Other associations of exocrine pancreatic insufficiency include (1) aplastic alae, aplasia cutis, deafness (Johanson-Blizzard syndrome); (2) sideroblastic anemia, developmental delay, seizures, and liver dysfunction (Pearson bone marrow pancreas syndrome); (3) duodenal atresia or stenosis; (4) malnutrition; and (5) pancreatic hypoplasia or agenesis.

The complications and sequelae of deficient pancreatic enzyme secretion are malnutrition, diarrhea, and growth failure. The degree of steatorrhea may lessen with age. Intragastric lipolysis primarily caused by lingual lipase may compensate in patients with low or absent pancreatic function. In Shwachman syndrome, the major sequela is short stature. Increased numbers of infections may result from chronic neutropenia. Neutrophil mobility is also impaired in many patients. In addition, an increased incidence of leukemia has been noted in these patients.

Pancreatic enzyme and fat-soluble vitamin replacement are required therapy in most patients. The prognosis appears to be good for those able to survive the increased number of bacterial infections early in life and those patients without severe associated defects.

ISOLATED EXOCRINE PANCREATIC ENZYME DEFECT

Normal premature infants and most newborns produce little, if any, pancreatic amylase following meals or exogenous hormonal stimulation. This temporary physiologic insufficiency may persist for the first 3–6 months of life and be responsible for diarrhea when complex carbohydrates (cereals) are introduced into the diet.

Congenital pancreatic lipase deficiency and congenital colipase deficiency are extremely rare disorders, causing diarrhea and variable malnutrition with malabsorption of dietary fat and fat-soluble vitamins. The sweat chloride level is normal, and neutropenia is absent. Treatment is oral replacement of pancreatic enzymes and a low-fat diet or formula containing medium-chain triglycerides.

Exocrine pancreatic insufficiency of proteolytic enzymes (eg, trypsinogen, trypsin, chymotrypsin) is caused by entero-kinase deficiency, a duodenal mucosal enzyme required for activation of the pancreatic proenzymes. These patients present with malnutrition associated with hypoproteinemia and edema but are free of respiratory symptoms and have a normal sweat test. They respond to pancreatic enzyme replacement therapy and feeding formulas that contain a casein hydrolysate (eg, Nutramigen, Pregestimil).

PANCREATIC TUMORS

Pancreatic tumors, whether benign or malignant, are rare. They most often arise from ductal or acinar epithelium (malignant adenocarcinoma) or from islet (endocrine) components within the gland, such as the benign insulinoma (adenoma) derived from β cells. Other pancreatic tumors also originate from these pluripotent endocrine cells (gastrinoma, VIPoma, glucagonoma). These malignant lesions produce diverse symptoms, because they release biologically active polypeptides from this ectopic location. The clinical features of these tumors are summarized in Table 21–10. The differential diagnosis of pancreatic tumors includes Wilms tumor, neuroblastoma, and malignant lymphoma. In older children, endoscopic ultrasonography can aid in localizing these tumors.

Kidney & Urinary Tract

Gary M. Lum, MD

EVALUATION OF THE KIDNEY & URINARY TRACT

HISTORY

When renal disease is suspected, the history should include:

1. Family history of cystic disease, hereditary nephritis, deafness, dialysis, or renal transplantation.
2. Preceding acute or chronic illnesses (e.g., urinary tract infection, pharyngitis, impetigo, or endocarditis).
3. Rashes or joint pains.
4. Growth delay or failure to thrive.
5. Polyuria, polydipsia, enuresis, urinary frequency, or dysuria.
6. Documentation of hematuria, proteinuria, or discolored urine.
7. Pain (abdominal, costovertebral angle, or flank) or trauma.
8. Sudden weight gain or edema.
9. Drug or toxin exposure.
10. Data pertaining to the newborn with suspected urinary tract disease: prenatal ultrasonographic studies, birth asphyxia, Apgar scores, oligohydramnios, dysmorphic features, abdominal masses, voiding patterns, anomalous development, and umbilical artery catheterization.

PHYSICAL EXAMINATION

Important aspects of the physical examination include the height, weight, skin lesions (café-au-lait or ash leaf spots), pallor, edema, or skeletal deformities. Anomalies of the ears, eyes, or external genitalia may be associated with renal anomalies or disease. The blood pressure should be measured in a quiet setting. The cuff should cover two thirds of the child’s upper arm, and peripheral pulses should be noted. The abdomen should be palpated, with attention to the kidneys, abdominal masses, musculature, and the presence of ascites. An ultrasonic device is useful for measurements in infants.

LABORATORY EVALUATION OF RENAL FUNCTION

Serum Analysis

The standard indicators of renal function are serum levels of urea nitrogen and creatinine; their ratio is normally about 10:1. This ratio may increase when renal perfusion or urine flow is decreased, as in urinary tract obstruction or dehydration. Because serum urea nitrogen levels are more affected by these and other factors (e.g., nitrogen intake, catabolism, use of corticosteroids) than are creatinine levels, the most reliable single indicator of glomerular function is the serum level of creatinine. For example, an increase in serum creatinine from 0.5 mg/dL to 1.0 mg/dL represents a 50% decrease in glomerular filtration rate. The serum creatinine level of small children should be well under 0.8 mg/dL. Only larger adolescents should have levels exceeding 1 mg/dL. Less precise but nonetheless important indicators of possible renal disease are abnormalities of serum electrolytes, pH, calcium, phosphorus, magnesium, albumin, or complement.

Glomerular Filtration Rate

The endogenous creatinine clearance (\(C_{\text{cr}}\)) in milliliters per minute estimates the glomerular filtration rate (GFR). A 24-hour urine collection is usually obtained; however, in small children from whom collection is difficult, a 12-hour daytime specimen, collected when urine flow rate is greatest, is acceptable. The procedure for collecting a timed urine specimen should be explained carefully so that the parent or patient understands fully the rationale of (1) first emptying the bladder (discarding that urine) and noting the time; and (2) putting all urine subsequently voided into the collection receptacle, including the last void, 12 or 24 hours later. Reliability of the 24-hour collection can be checked by measuring the total 24-hour creatinine excretion in the specimen. Total daily creatinine excretion (creatinine index) should be 14–20 mg/kg. Creatinine indices on either side of
this range suggest collections that were either inadequate or excessive. Calculation by the following formula requires measurements of plasma creatinine (\(P_{cr}\)) in mg/mL, urine creatinine (\(U_{cr}\)) in mg/mL, and urine volume (\(V\)) expressed as mL/min:

\[
C_{cr} = \frac{U_{cr} V}{P_{cr}}
\]

Creatinine is a reflection of body muscle mass. Because accepted ranges of normal \(C_{cr}\) are based on adult parameters, correction for size is needed to determine normal ranges in children. Clearance is corrected to a standard body surface area of 1.73 m\(^2\) in the formula:

\[
“Corrected”\ C = \frac{P_{cr} \times 1.73 \text{ m}^2}{\text{Patient’s body surface area}}
\]

Although 80–125 mL/min/1.73 m\(^2\) is the normal range for \(C_{cr}\), estimates at the lower end of this range may indicate problems.

A reliable formula for quick approximation of \(C_{cr}\) is based on plasma creatinine level and length in centimeters:

\[
C_{cr}(\text{mL/min}/1.73 \text{ m}^2) = 0.55 \times \text{Height in cm} \times \frac{P_{cr} \text{ in mg/dL}}{\text{P}_{cr}}
\]

**Note:** Because this formula takes into account the body surface area, further correction is not necessary. Use 0.45 \times length in centimeters for newborns and for infants younger than age 1 year. This method of calculation does not replace creatinine clearance determinations, but is useful when a suspicious plasma creatinine needs to be checked.

### Urine Concentrating Ability

Inability to concentrate urine causes polyuria, polydipsia, or enuresis and is often the first sign of chronic renal failure. The first morning void should be concentrated. Evaluation of other abnormalities of urinary concentration or dilution is discussed later in the sections on specific disease entities, such as diabetes insipidus.

### Urinalysis

Commercially available dipsticks can be used to check the urine for red blood cells (RBCs), hemoglobin, leukocytes, nitrites, and protein and to approximate its pH. Positive results for blood should always be confirmed by microscopy, as should any suspicion of crystalluria. Significant proteinuria (> 150 mg/dL) detected by dipstick should be confirmed by quantitation, either with a 24-hour collection or by the protein/creatinine ratio (see following section) of a random specimen.

In children with asymptomatic hematuria or proteinuria, the search for renal origins will yield the most results. Isolated proteinuria may reflect urologic abnormalities, benign excretion, or glomerular alterations. RBC casts suggest glomerulonephritis (GN), but the absence of casts does not rule out this disease. Anatomic abnormalities such as cystic disease may also cause hematuria.

Benign hematuria, including benign familial hematuria, is diagnosed by exclusion. In this group are children whose hematuria is caused by asymptomatic hypercalciuria. Figure 22–1 suggests an approach to the renal workup of hematuria. GN is discussed in more detail later in this chapter.

Combined proteinuria and hematuria is characteristic of more significant glomerular disease. Quantitation of proteinuria is customarily accomplished by a timed collection (eg, over a 24-hour period). However, the degree of proteinuria may be estimated by the ratio of protein/creatinine in a random urine sample. A protein-to-creatinine ratio above 0.2 is abnormal.

In the evaluation of asymptomatic proteinuria, orthostatic or postural proteinuria should be ruled out. The protein present in urine voided on arising in the morning is compared with that in urine formed in the upright position during the rest of the day. This can be accomplished simply by comparing the protein/creatinine ratios of the two urine samples. When quantitation is accomplished by evaluating the “upright” and “supine” portions of a 24-hour collection, a diagnosis of benign postural proteinuria is indicated if the upright collection contains 80–100% of the entire 24-hour protein excretion, and if there are no other markers of renal disease.

An approach to the workup of isolated proteinuria is shown in Figure 22–2. Note that corticosteroid therapy is indicated in the algorithm because this may be initiated prior to referral. Other renal lesions with proteinuric manifestations are discussed later in this chapter.

### Special Tests of Renal Function

Measurements of urinary sodium, creatinine, and osmolality are useful in differentiating prerenal from renal causes of renal insufficiency, such as acute tubular necrosis. The physiologic response to decreased renal perfusion is decreased urinary output, increased urine osmolality, increased urinary solutes (eg, creatinine), and decreased urinary sodium (usually < 20 mEq/L). Prolonged underperfusion causes varying increases in serum creatinine and blood urea nitrogen (BUN) concentrations, prompting the need to differentiate between this state and acute tubular necrosis (see section on Acute Renal Failure, later).

The presence of certain substances in urine may suggest tubular dysfunction. For example, urine glucose should be less than 5 mg/dL. Hyperphosphaturia occurs with significant tubular abnormalities (eg, Fanconi syndrome). Measurement of the phosphate concentration of a 24-hour urine specimen and evaluation of tubular reabsorption of phosphorus (TRP) will help document renal tubular diseases as
well as hyperparathyroid states. TRP (expressed as percentage of reabsorption) is calculated as follows:

$$\text{TRP} = 100 \left[ 1 - \frac{S_{cr} \times U_{PO_4}}{S_{PO_4} \times U_{cr}} \right]$$

where $S_{cr}$ = serum creatinine; $U_{cr}$ = urine creatinine; $S_{PO_4}$ = serum phosphate; and $U_{PO_4}$ = urine phosphate. All values for creatinine and phosphate are expressed in milligrams per deciliter for purposes of calculation. A TRP value of 80% or more is considered normal, although it depends somewhat on the value of $S_{PO_4}$.

The urinary excretion of amino acids in generalized tubular disease reflects a quantitative increase rather than a qualitative change. Diseases affecting proximal tubular reabsorption of bicarbonate—including isolated renal tubular acidosis (RTA), Fanconi syndrome (which occurs in diseases such as cystinosis), and chronic renal failure—are discussed later in the chapter.

### LABORATORY EVALUATION OF IMMUNOLOGIC FUNCTION

Many parenchymal renal diseases are thought to have immune causation, although the mechanisms are largely unknown. Examples include (1) deposition of circulating antigen-antibody complexes that are directly injurious or incite injurious responses and (2) formation of antibody directed against the glomerular basement membrane (rare in children).

Total serum complement and the C3 and C4 complement components should be measured when immune-mediated renal injury or chronic GN is suspected. Where clinically indicated, antinuclear antibodies, hepatitis B surface antigen, and rheumatoid factor should be obtained. In rare cases cold-
precipitable proteins (cryoglobulins), C3 “nephritic” factor, or antiglomerular basement membrane (anti-GBM) antibody measurements may help confirm a specific diagnosis. At some point in the workup, the diagnosis may be supported or confirmed by histologic examination of renal tissue.

**RADIOGRAPHIC EVALUATION**

Renal ultrasonography is a useful noninvasive tool for evaluating renal parenchymal disease, urinary tract abnormalities, or renal blood flow. Excretory urography is used to assess the anatomy and function of the kidney, collecting system, and bladder. Radioisotope studies provide information about renal anatomy, blood flow, and integrity and function of the glomerular, tubular, and collecting systems. Renal stones are best seen by computed tomography.

Voiding cystourethrography or cystoscopy is indicated when vesicoureteral reflux or bladder outlet obstruction is suspected. Cystoscopy is rarely useful in the evaluation of asymptomatic hematuria or proteinuria in children.
Renal arteriography or venography is indicated to define vascular abnormalities (eg, renal artery stenosis) prior to surgical intervention or transluminal angiography. Less invasive measures such as ultrasonography and Doppler studies can demonstrate renal blood flow or thromboses. More specific identification of stenoses of the renal artery is accomplished by magnetic resonance arteriography.

**RENAL BIOPSY**

Histologic information is valuable for diagnosis, treatment, and prognosis. Satisfactory evaluation of renal tissue requires examination by light, immunofluorescence, and electron microscopy.

When a biopsy is anticipated, a pediatric nephrologist should be consulted. In children, percutaneous renal biopsy with a biopsy needle is an acceptable low-risk procedure—avoiding the risks of general anesthesia—when performed by an experienced physician. A surgeon should perform the biopsy procedure if operative exposure of the kidney is necessary, if a risk factor (eg, bleeding disorder) is present, or if a “wedge” biopsy is preferred.

**CONGENITAL ANOMALIES OF THE URINARY TRACT**

**RENAL PARENCHYMAL ANOMALIES**

About 10% of children have congenital anomalies of the genitourinary tract, which range in severity from asymptomatic to lethal. Some asymptomatic abnormalities may have significant complications. For example, patients with “horse-shoe” kidney (kidneys fused in their lower poles) have a higher incidence of renal calculi. Unilateral agenesis is usually accompanied by compensatory hypertrophy of the contralateral kidney and thus should be compatible with normal renal function. Supernumerary and ectopic kidneys are usually of no significance. Abnormal genitourinary development is associated with varying degrees of renal dysgenesis and dysfunction ranging from mild forms to complete renal agenesis. In neonates, bilateral renal agenesis is associated with severe oligohydramnios, pulmonary hypoplasia, abnormal (Potter) facies, and early death.

1. **Renal Dysgenesis**

Renal dysgenesis is a spectrum of anomalies. In simple hypoplasia, which may be unilateral or bilateral, the affected kidneys are smaller than normal. In some forms of dysplasia, immature, undifferentiated renal tissue persists. In some dysplasias, the number of normal nephrons is insufficient to sustain life once the child reaches a critical body size. The lack of renal tissue may not be readily discernible in the newborn period because the infant’s urine production, though poor in concentration, may be adequate in volume. Often, the search for renal insufficiency is initiated only when growth fails or chronic renal failure develops.

Other forms of renal dysplasia include oligomeganephro-nia (characterized by the presence of only a few large glomeruli) and the cystic dysplasias (characterized by the presence of renal cysts). This group includes microcystic disease (congenital nephrosis). A simple cyst within a kidney may be clinically unimportant because it does not predispose to progressive polycystic development. An entire kidney lost to multicystic development with concomitant hypertrophy and normal function of the contralateral side may also be of little clinical consequence. Nonetheless, even a simple cyst could pose problems if it becomes a site for stone formation, infection, or bleeding.

2. **Polycystic Kidney Disease**

Autosomal recessive polycystic kidney disease is increasingly diagnosed by prenatal ultrasound. In its most severe form the cystic kidneys are nonfunctional in utero, and, therefore, newborns can have Potter facies and other complications of oligohydramnios. In infancy and childhood, kidney enlargement by cysts may initially be recognized by abdominal palpation of renal masses. Hypertension is an early problem. The rate of the progression of renal insufficiency varies, as does growth failure and other complications of chronic renal failure. Two genes (ADPKD1 and ADPKD2) account for 80% and 10% of cases of autosomal dominant polycystic kidney disease, respectively. Susceptibility of family members is detected by gene linkage studies. Renal ultrasound identifies cysts in about 80% of affected children by age 5 years. Children with this diagnosis need close monitoring for the development and treatment of hypertension, and their families should be offered genetic counseling. Management of end-stage renal failure is by dialysis or renal transplantation.

3. **Medullary Cystic Disease (Juvenile Nephronophthisis)**

Medullary cystic disease is characterized by cysts of varying sizes in the renal medulla with tubular and interstitial nephritis. Children present with renal failure and signs of tubular dysfunction (decreased concentrating ability, Fanconi syndrome). This lesion should not be confused with medullary sponge kidney (renal tubular ectasia), a frequently asymptomatic disease occurring in adults.

**DISTAL URINARY TRACT ANOMALIES**

1. **Obstructive Uropathy**

Obstruction at the ureteropelvic junction may be the result of intrinsic muscle abnormalities, aberrant vessels, or fibrous bands. The lesion can cause hydronephrosis and usually presents as an abdominal mass in the newborn. Obstruction
can occur in other parts of the ureter, especially at its entrance into the bladder, causing proximal hydroureter and hydrenephrosis. Renal radionuclide scan with furosemide “wash-out” will reveal or rule out obstruction as the cause of the hydrenephrosis. Whether intrinsic or extrinsic, urinary tract obstruction should be relieved surgically as soon as possible to minimize damage to the kidneys.

Severe bladder malformations such as extrophy are clinically obvious and a surgical challenge. More subtle—but urgent in terms of diagnosis—is obstruction of urine flow from vestigial posterior urethral valves. This anomaly, which occurs almost exclusively in males, usually presents in newborns with anuria or a poor voiding stream secondary to severe obstruction of urine flow. The kidneys and bladder may be easily palpable. Leakage proximal to the obstruction may produce urinary ascites. Surgical drainage of urine is urgently required to prevent irreversible damage.

Prune belly syndrome is an association of urinary tract anomalies with cryptorchidism and absent abdominal musculature. Although complex anomalies, especially renal dysplasia, usually cause early death or the need for dialysis or transplantation, some patients have lived into the third decade with varying degrees of renal insufficiency. Timely urinary diversion is essential to sustain renal function.

Other complex malformations and external genital anomalies such as hypospadias are beyond the scope of this text. The challenge presented by urologic abnormalities resulting in severe compromise and destruction of renal tissue is to preserve all remaining renal function and treat the complications of progressive chronic renal failure. Involvement of a specialist in pediatric urology in early management is essential.

2. Reflux Nephropathy

The retrograde flow of urine from the bladder into the ureter (vesicoureteral reflux), may cause renal scarring and subsequent renal insufficiency or hypertension, or both, especially in the presence of urinary tract infection. A finding of hydrenephrosis on renal ultrasound is suggestive of vesicoureteral reflux. Its presence can be confirmed or eliminated by a voiding cystourethrogram, which would also be obtained to rule out reflux in the evaluation of urinary tract infection. Low-grade reflux may resolve in the absence of infection, in which case antibiotic prophylaxis is undertaken while awaiting signs of resolution. Surgery may be required for chronic severe reflux.

HEMATURIA & GLOMERULAR DISEASE

MICROHEMATURIA

Children with painful hematuria should be investigated for uretric tract infection or direct injury to the urinary tract. Dysuria is common in cystitis or urethritis; associated back pain suggests the possibility of pyelonephritis; colicky flank pain may indicate the passage of a stone. Bright red blood or clots in the urine are associated with bleeding disorders, trauma, and arteriovenous malformations. Abdominal masses suggest the presence of urinary tract obstruction, cystic disease, or tumors of the renal or perirenal structures.

Asymptomatic hematuria is a challenge because clinical and diagnostic data are required to decide whether to refer the child to a nephrologist. The diagnosis of hematuria should not rely solely on a urine “dipstick” evaluation, but should be verified by a microscopic RBC count. Ruling out hypercalciuria as a cause of hematuria by a random urine calcium/creatinine ratio is one of the initial steps in the evaluation of hematuria. A value above 0.2 requires verification with a 24-hour collection. Hypercalciuria is excretion of calcium in excess of 4 mg/kg/d. Figure 22–1 delineates the outpatient approach to renal hematuria. The concern regarding the differential diagnosis is the possible presence of glomerular disease.

GLOMERULONEPHRITIS

The various types of GN have similar manifestations. Table 22–1 lists the most commonly encountered disorders in the differential diagnosis of childhood GN, including their clinical and histopathologic abnormalities. Severe glomerular histopathologic and clinical entities, such as anti-GBM antibody disease (Goodpasture syndrome), Wegener granulomatosis, and idiopathic, rapidly progressive GN, may be considered in the differential diagnosis of acute GN, but these disorders are exceedingly rare in children.

1. Poststreptococcal Glomerulonephritis

The diagnosis of poststreptococcal disease is supported by a recent history (7–14 days previously) of group A β-hemolytic streptococcal infection. If a positive culture is not available, recent infection may be supported by an elevated antistreptolysin O titer or by high titers of other antistreptococcal antibodies. Other infections can cause similar glomerular injury; thus, “postinfection” glomerulonephritis (GN) may be a better term for this type of acute GN. In most cases, recovery is expected and usually complete within weeks. If the diagnosis is in question, or if the renal function of a patient with postinfection GN progressively deteriorates, a renal biopsy should be performed.

The clinical presentation of GN is usually gross hematuria. Urine may be coffee-colored or tea-colored. Microscopic examination of urine reveals RBCs too numerous to
Table 22-1. Glomerular diseases encountered in childhood.

<table>
<thead>
<tr>
<th>Entity</th>
<th>Clinical Course</th>
<th>Prognosis</th>
</tr>
</thead>
<tbody>
<tr>
<td>Postinfection glomerulonephritis (GN).</td>
<td>Acute phase is usually over in 2 wk. Complete resolution occurs in 95% of cases.</td>
<td>Excellent. Chronic disease is rare. Severe proteinuria, atypical presentation or course, or persistent hypocomplementemia suggest another entity.</td>
</tr>
<tr>
<td>Membranoproliferative GN.</td>
<td>Course can be mild to severe (rapid deterioration in renal function); may mimic postinfection GN. Proteinuria can be severe. Complement depression is intermittent to persistent. Hypertension is usually significant.</td>
<td>Type I may respond to corticosteroids. Type II (dense deposit disease) is less treatable; function decrease varies from immediate to as long as 15 y in 30-50% of untreated cases.</td>
</tr>
<tr>
<td>IgA nephropathy.</td>
<td>90% of cases resolve in 1-5 y. Gross hematuric episodes resolve with recovery from acute illness. Severity of renal insufficiency and hypertension varies. Proteinuria occurs in more severe, atypical cases.</td>
<td>Generally good; a small percentage develops chronic renal failure. Proteinuria in the nephrotic range is a poor sign. There is no universally accepted medication. (Corticosteroids may be useful in severe cases.)</td>
</tr>
<tr>
<td>Henoch-Schönlein purpura GN.</td>
<td>Presentation varies with severity of renal lesion. In rare cases, may progress rapidly to serious renal failure. Hypertension varies. Proteinuria in the nephrotic range and severe decline in function can occur.</td>
<td>Overall, prognosis is good. Patients presenting with &gt; 50% reduction in function or proteinuria exceeding 1 g/24 h may develop chronic renal failure. Severity of renal biopsy picture can best guide approach in such cases. There is no universally accepted medication.</td>
</tr>
<tr>
<td>GN of systemic lupus erythematosus (SLE).</td>
<td>Renal involvement is mild to severe. Clinical complexity depends on degree of renal insufficiency and other systems involved. Hypertension is significant. Manifestations of the severity of the renal lesion guide therapeutic intervention.</td>
<td>Renal involvement accounts for most significant morbidity in SLE. Control of hypertension affects renal prognosis. Medication is guided by symptoms, serology, and renal lesion. End-stage renal failure can occur.</td>
</tr>
<tr>
<td>Hereditary GN (eg, Alport syndrome).</td>
<td>There is no acute syndrome. Females are generally less affected but are carriers. Hypertension and increasing proteinuria occur with advancing renal failure. There is no known treatment.</td>
<td>Progressive proteinuria and hypertension occur early, with gradual decline in renal function in those most severely affected. Disease progresses to end-stage renal failure in most males.</td>
</tr>

</table>

count. Microscopy may reveal RBC casts. If present, these are diagnostic of GN, but their absence does not exclude the diagnosis. Edema is often seen (periorbital, facial, extremities), caused by sodium and water retention resulting from alteration in glomerular function. Symptoms are usually nonspecific. In cases accompanied by hypertension (a common finding), headache may be present. Fever is uncommon. Severe glomerular injury (which usually occurs in severe, acute presentations of the more chronic or destructive forms of GN) may be accompanied by massive proteinuria (nephrotic syndrome), anasarca, ascites, and severe compromise of renal function.

Typical poststreptococcal GN has no specific treatment. Antibiotic therapy is indicated if an infection is still present. Disturbances in renal function and resulting hypertension may require close monitoring, reduction in salt intake, diuretics or other antihypertensive drugs. In severe cases of renal failure, hemodialysis or peritoneal dialysis may be necessary. Corticosteroids may also be administered in an attempt to influence the course of the GN.

The acute abnormalities generally resolve in 2–3 weeks. Serum complement (C3) may be normal as early as 3 days or as late as 30 days after onset. Complement-consuming glomerulonephritides also include membranoproliferative GN (chronic GN with persistent complement depression) and lupus GN. (See Chapter 27.) Although microscopic hematuria may persist for as long as a year, 85% of children recover completely. Persistent deterioration in renal function, urinary abnormalities beyond 18 months, persistent hypocomplementemia, and nephrotic syndrome are ominous signs. If any of these is present, a renal biopsy is indicated.

2. IgA Nephropathy

When asymptomatic gross hematuria appears to accompany a minor acute febrile illness or other stressful occurrence, the
diagnosis of IgA nephropathy may be entertained. In contrast to postinfection GN, IgA nephropathy is not associated with prior streptococcal infection, complement is not depressed, and in 50% of cases, serum immunoglobulin A is elevated. Often there are no associated symptoms or signs. Gross hematuria resolves within days, and there are no serious sequelae in 85% of cases. Treatment is not indicated, and the prognosis is good in most cases. Prognosis is guarded, however, if severe proteinuria, hypertension, or renal insufficiency is present or develops. In such instances, although no treatment is universally accepted, corticosteroids and other immunosuppressive drugs are used. Omega-3 fatty acids from fish oils are thought to be helpful.

3. Henoch-Schönlein Purpura

The diagnosis of Henoch-Schönlein purpura rests on the presence of a typical maculopapular rash found primarily, but not exclusively, on the dorsal surfaces of the lower extremities and buttocks. Most children have abdominal pain and bloody diarrhea. Joint pain is common, and, depending on the extent of renal involvement, hypertension may be present. Joint and abdominal pain responds to treatment with corticosteroids. Renal involvement ranges from mild GN with microhematuria to severe GN and varying degrees of renal insufficiency. GN with massive proteinuria and renal insufficiency carries a poor prognosis. Twenty percent of such cases result in end-stage renal failure. There is no universally accepted treatment, but corticosteroids are often administered (see Chapter 28).

4. Membranoproliferative Glomerulonephritis

The most common “chronic” form of GN in childhood is membranoproliferative GN. The diagnosis is established from the histologic appearance of the glomeruli on biopsy tissue. There are two major histologic types of membranoproliferative GN. Clinically, type II carries the worse prognosis, as end-stage renal failure develops in most cases. Type I more often responds to treatment with corticosteroids. C3 is depressed (in both types) and may be useful as a marker of response to treatment.

5. Lupus Glomerulonephritis

The diagnosis of systemic lupus erythematosus is based on its numerous clinical features and abnormal laboratory findings that include a positive antinuclear antibody test, depressed serum complement, and increased serum double-stranded DNA. Renal involvement is indicated by varying degrees of hematuria and proteinuria. More severe cases are accompanied by renal insufficiency and hypertension. Significant renal involvement requires treatment with immunosuppressive drugs and close monitoring. End-stage renal failure develops in 10–15% of patients with childhood SLE.

6. Hereditary Glomerulonephritis

The most commonly encountered hereditary glomerulonephritis is Alport syndrome, characterized by hearing loss and GN, occurring predominantly in males. It is a chronic form of GN and thus does not present with the clinical features typically seen in patients with acute processes. A family history is generally present, but there is a spontaneous mutation rate of about 18%. In individuals with the progressive form of GN, end-stage renal failure occurs, usually in the second to third decade of life. Although currently there is no treatment for this disorder, careful management of associated hypertension may slow the process.

ACUTE INTERSTITIAL NEPHRITIS

Acute interstitial nephritis is characterized by diffuse or focal inflammation and edema of the renal interstitium and secondary involvement of the tubules. The condition is most commonly drug related (e.g., β-lactam–containing antibiotics, such as methicillin).

Fever, rigor, abdominal or flank pain, and rashes may occur in drug-associated cases. Urinalysis usually reveals leukocyturia and hematuria. Hansel staining of the urinary sediment often demonstrates eosinophils. The inflammation can cause significant deterioration of renal function. If the diagnosis is unclear because of the absence of a history of drug or toxin exposure or the absence of eosinophils in the urine, a renal biopsy may be performed to demonstrate the characteristic tubular and interstitial inflammation. Immediate identification and removal of the causative agent is imperative and may be all that is necessary. Treatment with corticosteroids is helpful in patients with progressive renal insufficiency or nephrotic syndrome. Severe renal failure requires supportive dialysis.

PROTEINURIA & RENAL DISEASE

Urine is rarely completely protein-free, but the average excretion is well below 150 mg/24 h. Small increases in urinary protein can accompany febrile illnesses or exertion and in some cases occur while in the upright posture.

An algorithm for investigation of isolated proteinuria is presented in Figure 22–2. In idiopathic nephrotic syndrome without associated features of GN, treatment with corticosteroids may be initiated. Nephrologic advice or follow-up should be sought, especially in patients with difficult or frequently relapsing unexplained proteinuria.
CONGENITAL NEPHROSIS

Congenital nephrosis is a rare autosomal recessive disorder. The kidneys are pale and large and may show microcystic dilations (microcystic disease) of the proximal tubules and glomerular abnormalities, including proliferation, crescent formation, and thickening of capillary walls. The pathogenesis is not well understood.

Infants with congenital nephrosis commonly have low birth weight, a large placenta, wide cranial sutures, and delayed ossification. Mild edema may be seen after the first few weeks of life. Anasarca follows, and the abdomen can become greatly distended by ascites. Massive proteinuria associated with typical-appearing nephrotic syndrome and hyperlipidemia is the rule. Hematuria is common. If the patient lives long enough, progressive renal failure occurs. Most affected infants succumb to infections at the age of a few months.

Treatment prior to dialysis and transplantation has little to offer other than nutritional support and management of the chronic renal failure.

IDIOPATHIC NEPHROTIC SYNDROME OF CHILDHOOD (NIL DISEASE, LIPOID NEPHROSIS, MINIMAL CHANGE DISEASE)

Nephrotic syndrome is characterized by proteinuria, hypoalbuminemia, edema, and hyperlipidemia. It may occur as a result of any form of glomerular disease and may rarely be associated with a several extrarenal conditions. In young children, the disease usually takes the form of idiopathic nephrotic syndrome of childhood (nil disease, lipid nephrosis, minimal change disease), which has characteristic clinical and laboratory findings, but no well-understood cause.

Clinical Findings

Affected patients are generally younger than age 6 years at onset. Typically, periorbital swelling and oliguria are noted, often following an influenza-like syndrome. Within a few days, increasing edema—even anasarca—becomes evident. Most children have few complaints other than vague malaise or abdominal pain. With significant “third spacing” of plasma volume, however, some children may present with hypotension. With marked edema, dyspnea due to pleural effusions may also occur.

Despite heavy proteinuria, the urine sediment is usually normal, although microscopic hematuria may be present. Plasma albumin concentration is low, and lipid levels increased. When azotemia occurs, it is usually secondary to intravascular volume depletion.

Glomerular morphology is unremarkable except for fusion of foot processes of the glomerular basement membrane. This nonspecific finding is associated with many proteinuric states.

Complications

Infections (eg, peritonitis) sometimes occur, and pneumococci are frequently the cause. Hypercoagulability may be present, and thromboembolic phenomena are commonly reported. In patients with minimal change disease, hypertension can still be noted, and renal insufficiency can result from decreased renal perfusion.

Treatment & Prognosis

As soon as the diagnosis of idiopathic nephrotic syndrome is made, corticosteroid treatment should be started. Prednisone, 2 mg/kg/d (maximum, 60 mg/d), is given for 6 weeks as a single daily dose. The same dose is then administered on an alternate-day schedule for 6 weeks; thereafter, the dose is tapered gradually and discontinued over the ensuing 2 months. The goal of this regimen is the disappearance of proteinuria. If remission is not achieved during the initial phase of corticosteroid treatment, additional nephrologic consultation should be obtained. If remission is achieved, only to be followed by relapse, the treatment course may be repeated. A renal biopsy is often considered when there is little or no response to treatment. One should take into account that the histologic findings may not alter the treatment plan, which is designed to eliminate the nephrotic syndrome regardless of underlying renal histology.

Unless the edema causes symptoms such as respiratory compromise due to ascites, diuretics should be used with extreme care. Patients may have decreased circulating volume and are also at risk for intravenous thrombosis. Careful restoration of compromised circulating volume with intravenous albumin infusion and administration of diuretics is helpful in mobilizing edema. Infections such as peritonitis should be treated promptly to reduce morbidity. Immunization with pneumococcal vaccine is advised.

A favorable response of proteinuria to corticosteroids and subsequent favorable response during relapse suggests a good prognosis. Failure to respond or early relapse usually heralds a prolonged series of relapses. This not only may indicate the presence of more serious nephropathy, but presents a challenge in choosing future therapy. Chlorambucil or cyclophosphamide drug therapy is usually effective only in children who respond to corticosteroids. Patients who do not respond to corticosteroids or who relapse frequently should be referred to a pediatric nephrologist. Intravenous Solu-Medrol may be helpful in more refractory cases. When the protracted use of corticosteroids raises concerns of toxicity, concomitant treatment with either cyclosporin A or tacrolimus appears to be helpful.

FOCAL GLOMERULAR SCLEROSIS

Focal glomerular sclerosis is one cause of corticosteroid-resistant or frequent relapsing nephrotic syndrome. The cause is unknown. The diagnosis is made by renal biopsy,
which shows normal-appearing glomeruli as well as some partially or completely sclerosed glomeruli. The lesion has serious prognostic implications because as many as 15–20% of cases can progress to end-stage renal failure. The response to corticosteroid treatment is variable. In difficult cases, cyclosporin A or tacrolimus have been used in addition to corticosteroids. There are increasing reports that poorly responsive cases may respond to rituximab, a monoclonal antibody against the B-cell surface antigen CD20. Recurrence of focal glomerular sclerosis may occur after renal transplantation. The recurrence is usually treated with plasmapheresis or rituximab (this drug is finding encouraging utility in membranous or mesangial nephropathy as well as minimal change disease).

MESANGIAL NEPHROPATHY (MESANGIAL GLOMERULONEPHRITIS)

Mesangial nephropathy is another form of corticosteroid-resistant nephrotic syndrome. The renal biopsy shows a distinct increase in the mesangial matrix of the glomeruli. Very often the expanded mesangium contains deposits of IgM demonstrable on immunofluorescent staining. The cause is unknown. Corticosteroid therapy may induce remission, but relapses are common. Choices for treating this type of nephrotic syndrome are the same as noted earlier.

MEMBRANOUS NEPHROPATHY (MEMBRANOUS GLOMERULONEPHRITIS)

Although largely idiopathic in nature, membranous nephropathy can be found in association with hepatitis B antigenemia, systemic lupus erythematosus, congenital and secondary syphilis, renal vein thrombosis; with immunologic disorders such as autoimmune thyroiditis; and with administration of drugs such as penicillamine. The pathogenesis is unknown, but the glomerular lesion is thought to be the result of prolonged deposition of circulating antigen–antibody complexes.

The onset of membranous nephropathy may be insidious or may resemble that of idiopathic nephrotic syndrome of childhood (see earlier section). It occurs more often in older children and adults. The proteinuria of membranous nephropathy responds poorly to corticosteroid therapy, although low-dose corticosteroid therapy may reduce or delay development of chronic renal insufficiency. The diagnosis is made by renal biopsy.

In new borns, renal vein thrombosis may complicate sepsis or dehydration. It may be observed in infants of diabetic mothers; may be associated with umbilical vein catheterization; or may result from any condition that produces a hypercoagulable state (eg, clotting factor deficiency, systemic lupus erythematosus, or thrombocytosis). Renal vein thrombosis is less common in older children and adolescents. It may develop following trauma or without any apparent predisposing factors. Spontaneous renal vein thrombosis has been associated with membranous glomerulonephropathy. Nephrotic syndrome may either cause or result from renal vein thrombosis.

Clinical Findings

Renal vein thrombosis in new borns is generally characterized by the sudden development of an abdominal mass. If the thrombosis is bilateral, oliguria may be present; urine output may be normal with a unilateral thrombus. In older children, flank pain, sometimes with a palpable mass, is a common presentation.

No single laboratory test is diagnostic of renal vein thrombosis. Hematuria usually is present; proteinuria is less constant. In the new born, thrombocytopenia may be found, but it is rare in older children. The diagnosis is made by ultrasonography and Doppler flow studies.

Treatment

Anticoagulation with heparin is the treatment of choice in new borns and older children. In the new born, a course of heparin combined with treatment of the underlying problem is usually all that is required. Management in other cases is less straightforward. The tendency for recurrence and embolization has led some to recommend long-term anticoagulation. If an underlying membranous GN is suspected, biopsy should be performed.

Course & Prognosis

The mortality rate in new borns from renal vein thrombosis depends on the underlying cause. With unilateral thromboses, the prognosis for adequate renal function is good. Renal vein thrombosis may rarely recur in the same kidney or occur in the other kidney years after the original episode of thrombus formation. Extension into the vena cava with pulmonary emboli is possible.

RENA L ARTERIAL DISEASE

Arterial disease (eg, fibromuscular hyperplasia, congenital stenosis) is a rare cause of hypertension in children. Although few clinical clues are specific to underlying arterial lesions, they should be suspected in children with severe hypertension, with onset at or before age 10 years, or with delayed visualization on nuclear scan of the kidneys. The

hemolytic uremic syndrome is the most common glomerular vascular cause of acute renal failure in childhood. It is usually the result of infection with Shigatoxin-producing (also called verotoxin-producing) strains of Shigella or Escherichia coli. Ingestion of undercooked ground beef or unpasteurized foods is a common source. There are many serotypes, but the most common pathogen in the United States is E coli O157:H7. Bloody diarrhea is the usual presenting complaint, followed by hemolysis and renal failure. Circulating verotoxin causes endothelial damage, which leads to platelet deposition, microvascular occlusion with subsequent hemolysis, and thrombocytopenia. Similar microvascular endothelial activation may also be triggered by drugs (eg, cyclosporin A); by viruses (HIV); and by pneumococcal infections, in which bacterial neuraminidase exposes the Thomsen-Friedenreich antigen on RBCs, platelets, and endothelial cells, thereby causing platelet aggregation, endothelial damage, and hemolysis. Rare cases are caused by genetic factors (eg, congenitally depressed C3 complement and factor H deficiency).

**HEMOLYTIC-UREMIC SYNDROME**

Hemolytic-uremic syndrome is the most common glomerular vascular cause of acute renal failure in childhood. It is usually the result of infection with Shigatoxin-producing (also called verotoxin-producing) strains of Shigella or Escherichia coli. Ingestion of undercooked ground beef or unpasteurized foods is a common source. There are many serotypes, but the most common pathogen in the United States is E coli O157:H7. Bloody diarrhea is the usual presenting complaint, followed by hemolysis and renal failure. Circulating verotoxin causes endothelial damage, which leads to platelet deposition, microvascular occlusion with subsequent hemolysis, and thrombocytopenia. Similar microvascular endothelial activation may also be triggered by drugs (eg, cyclosporin A); by viruses (HIV); and by pneumococcal infections, in which bacterial neuraminidase exposes the Thomsen-Friedenreich antigen on RBCs, platelets, and endothelial cells, thereby causing platelet aggregation, endothelial damage, and hemolysis. Rare cases are caused by genetic factors (eg, congenitally depressed C3 complement and factor H deficiency).

**Clinical Findings**

The epidemic form begins with a prodrome of abdominal pain, diarrhea, and vomiting. Oliguria, pallor, and bleeding manifestations, principally gastrointestinal, occur next. Hypertension and seizures develop in some children—especially those who develop severe renal failure and fluid overload. There may also be significant endothelial involvement in the central nervous system (CNS).

Anemia is profound, and RBC fragments are seen on blood smears. A high reticulocyte count confirms the hemolytic nature of the anemia, but may not be noted in the presence of renal failure. Thrombocytopenia is profound, but other coagulation abnormalities are less consistent. Serum fibrin split products are often present, but fulminant disseminated intravascular coagulation is rare. Hematuria and proteinuria are often present. The serum complement level is normal except in those cases related to congenital predisposition.

**Complications**

These usually result from renal failure. Neurologic problems, particularly seizures, may result from hyponatremia, hyper-tension, or CNS vascular disease. Severe bleeding, transfusion requirements, and hospital-acquired infections must be anticipated.

**Treatment**

Meticulous attention to fluid and electrolyte status is crucial. The use of antimotility agents and antibiotics is believed to worsen the disease. Antibiotics may up-regulate and cause the release of large amounts of bacterial Shiga toxin. Timely dialysis improves the prognosis. Since prostacyclin-stimulating factor, a potent inhibitor of platelet aggregation, may be absent in some cases, plasma infusion or plateletpheresis has been advocated in severe cases (generally in those cases with severe CNS involvement). Platelet inhibitors have also been tried, but the results have not been impressive, especially late in the disease. Nonetheless, using a platelet inhibitor early in the disease in an attempt to halt platelet consumption and microvascular occlusion may obviate the need for platelet transfusions and reduce the progression of renal failure. RBC and platelet transfusions may be necessary. Although the risk of volume overload is significant, this can be minimized by dialysis. Erythropoietin (epoetin alfa) treatment may reduce RBC transfusion needs. Although no therapy is universally accepted, strict control of hypertension, adequate nutrition support, and the timely use of dialysis reduce morbidity and mortality. If renal failure is “nonoliguric,” and if urine output is sufficient to ensure against fluid overload and electrolyte abnormalities, management of renal failure without dialysis is possible.

**Course & Prognosis**

Most commonly, children recover from the acute episode within 2–3 weeks. Some residual renal disease (including hypertension) occurs in about 30%, and end-stage renal failure occurs in about 15%. Thus follow-up of children recovering from hemolytic-uremic syndrome should include serial determinations of renal function for 1–2 years and monitoring of blood pressure for 5 years. Mortality (about 3–5%) is most likely in the early phase, primarily resulting from CNS or cardiac complications.

dration. However, encountering signs of acute renal insufficiency in a hospitalized patient raises many other possibilities: impaired renal perfusion or renal ischemia, acute renal disease, renal vascular compromise, acute tubular necrosis, or obstructive uropathy. Table 22–2 lists such prerenal, renal, and postrenal causes.

Clinical Findings

The hallmark of early renal failure is oliguria. Although an exact etiologic diagnosis may be unclear at the onset, classifying oliguria as outlined in Table 22–2 is helpful in determining if an immediately reversible cause is present.

If the cause of elevation in serum BUN and creatinine or oliguria is unclear, entities that can be quickly addressed and corrected (eg, volume depletion) should be considered first. Once normal renal perfusion is ensured and no clinical evidence for de novo renal disease is present, a diagnosis of acute tubular necrosis (vasomotor nephropathy, ischemic injury) may be entertained.

A. Prerenal Causes

The most common cause of decreased renal function in children is compromised renal perfusion. It is usually secondary to dehydration, although abnormalities of renal vasculature and poor cardiac performance may also be considered. Table 22–3 lists the urinary indices helpful in distinguishing these “prerenal” conditions from true renal parenchymal insult, such as in acute tubular necrosis.

B. Renal Causes

Causes of renal failure intrinsic to the kidney include acute glomerulonephritides, hemolytic-uremic syndrome, acute interstitial nephritis, and nephrotoxic injury. The diagnosis of acute tubular necrosis (vasomotor nephropathy)—which is reserved for those cases in which renal ischemic insult is believed to be the likely cause—should be considered when correction of prerenal or postrenal problems does not improve renal function and there is no evidence of de novo renal disease.

C. Postrenal Causes

Postrenal failure, usually found in newborns with urologic anatomic abnormalities, is accompanied by varying degrees of renal insufficiency. The approach to the problem in the very young is addressed earlier in the chapter, but one should always keep in mind the possibility of acute urinary tract obstruction in acute renal failure, especially in the setting of anuria of acute onset.

Complications

The clinical severity of the complications depends on the degree of renal functional impairment and oliguria. Common complications include (1) fluid overload (hypertension, congestive heart failure, pulmonary edema), (2) electrolyte disturbances (hyperkalemia), (3) metabolic acidosis, (4) hyperphosphatemia, and (5) uremia.

Treatment

An indwelling bladder catheter is inserted to ascertain urine output. If urine volume is insignificant and renal failure is established, the catheter should be removed to minimize infection risk. Prerenal or postrenal factors should be excluded or rectified, and normal circulating volume maintained with
appropriate fluids. Strict measurement of input and output must be maintained, and input adjusted as reduction in output dictates. The patient’s response is assessed by physical examination and urinary output. Measurement of central venous pressure may be indicated. Increasing urine output with diuretics, such as furosemide (1–5 mg/kg, per dose, intravenously, maximum of 200 mg), can be attempted. The effective dose will depend on the amount of functional compromise (if < 50% function, initiate attempt at diuresis with maximum dose). If a response does not occur within 1 hour and the urine output remains low (< 0.5 mL/kg/h), the furosemide dose, if not already maximized, should be increased up to 5 mg/kg. In some cases the addition of a long-acting thiazide diuretic, such as metolazone, may improve the response. If no diuresis occurs with maximum dosing, further administration of diuretics should cease.

If these maneuvers stimulate some urine flow but biochemical evidence of acute renal failure persists, the resulting non-oliguric acute renal failure should be more manageable. Fluid overload and dialysis may be averted. However, if the medications and nutrients required exceed the urinary output, dialysis is indicated. Institution of dialysis before the early complications of acute renal failure develop is likely to improve clinical management and outcome. It is important to adjust medication dosage according to the degree of renal function.

A. Acute Dialysis: Indications
Immediate indications for dialysis are (1) severe hyperkalemia; (2) unrelenting metabolic acidosis (usually in a situation where fluid overload prevents sodium bicarbonate administration); (3) fluid overload with or without severe hypertension or congestive heart failure (a situation that would seriously compromise nutrition or drug administration); and (4) symptoms of uremia, usually manifested in children by CNS depression.

B. Methods of Dialysis
Peritoneal dialysis is generally preferred in children because of the ease of performance and patient tolerance. Although peritoneal dialysis is technically less efficient than hemodialysis, hemodynamic stability and metabolic control can be better sustained because this technique can be applied on a relatively continuous basis. Hemodialysis should be considered (1) if rapid removal of toxins is desired, (2) if the size of the patient makes hemodialysis less technically cumbersome and hemodynamically well tolerated, or (3) if impediments to efficient peritoneal dialysis are present (eg, ileus, adhesions). Furthermore, if vascular access and usage of anticoagulation are not impediments, a slow, continuous hemodialytic process (continuous renal replacement treatment) may be applied.

C. Complications of Dialysis
Complications of peritoneal dialysis include peritonitis, volume depletion, and technical complications such as dialysate leakage and respiratory compromise from intra-abdominal dialysate fluid. Peritonitis can be avoided by strict aseptic technique. Peritoneal fluid cultures are obtained as clinically indicated. Leakage is reduced by good catheter placement technique and appropriate intra-abdominal dialysate volumes. Dialysis is useful in maintaining electrolyte balance. Potassium (absent from standard dialysate solutions) can be added to the dialysate as required. Phosphate is also absent because hyperphosphatemia is an expected problem in renal failure. Nonetheless, if phosphate intake is inadequate, hypophosphatemia must be addressed. Correction of fluid overload is accomplished by using high osmolar dialysis fluids. Higher dextrose concentrations (maximum 4.25%) can correct fluid overload rapidly at the risk of causing hyperglycemia. Fluid removal may also be increased with more frequent exchanges of the dialysate, but rapid osmotic transfer of water may result in hypernatremia.

Even in small infants, hemodialysis can rapidly correct major metabolic and electrolyte disturbances, as well as volume overload. The process is highly efficient, but the speed of the changes can cause problems such as hemodynamic instability. Anticoagulation is usually required. Careful monitoring of the appropriate biochemical parameters is important. Note that during or immediately following the procedure, blood sampling will produce misleading results because equilibration between extravascular compartments and the blood will not have been achieved. Vascular access must be obtained and carefully monitored.

Course & Prognosis
If severe oliguria occurs, it usually lasts about 10 days. Anuria or oliguria lasting longer than 3 weeks makes the diagnosis of acute tubular necrosis unlikely and favors alternative diagnoses such as vascular injury, severe ischemia (cortical necrosis), GN, or obstruction. The diuretic phase begins with an increase in urinary output to large volumes of isosthenuric urine containing sodium levels of 80–150 mEq/L. During the recovery phase, signs and symptoms subside rapidly, although polyuria may persist for several days or weeks. Urinary abnormalities usually disappear completely within a few months. If renal recovery does not ensue, arrangements are made for chronic dialysis and eventual renal transplantation.

Chronic renal failure in children most commonly results from developmental abnormalities of the kidneys or urinary tract. Infants with renal agenesis are not expected to survive. Depending on the degree of dysgenesis (including multicystic development) the resulting renal function will determine
outcome. Abnormal development of the urinary tract may not permit normal renal development. Obstructive uropathy or severe vesicoureteral reflux nephropathy, without (or despite) surgical intervention, continues to cause a significant amount of progressive renal insufficiency in children. In older children, the chronic glomerulonephritides and nephropathies, irreversible nephrotoxic injury, or hemolytic-uremic syndrome may also cause chronic renal failure.

When chronic renal failure is congenital, the inability to concentrate urine results in polyuria. Affected patients often fail to thrive. Without medical care, children with longstanding chronic renal failure may present with complications such as rickets or anemia.

Chronic renal failure may follow acute GN or develop with chronic GN in the absence of an obvious acute episode. Growth failure depends on age at presentation and the rapidity of functional decline. Some of the chronic glomerulonephritides (eg, membranoproliferative GN) can progress unnoticed if subtle abnormalities of the urinary sediment are undetected or ignored. Any child with a history of chronic GN or significant renal injury needs close follow-up and monitoring of renal function and blood pressure.

**Complications**

Any remaining unaffected renal tissue can compensate for gradual loss of functioning nephrons in progressive chronic renal failure, but complications of renal insufficiency appear when compensatory ability is overwhelmed. In children who have developmentally reduced function and are unable to concentrate the urine, polyuria and dehydration are more likely to be problems than fluid overload. Output may be expected to gradually diminish as renal failure progresses to end stage; however, some children can continue to produce generous quantities of urine (but not of good quality) even though they require dialysis. A salt-wasting state can also occur. In contrast, children who develop chronic renal failure due to glomerular disease or renal injury will characteristically retain sodium and water and develop hypertension.

Metabolic acidosis and growth retardation occur early in chronic renal failure. Disturbances in calcium, phosphorus, and vitamin D metabolism leading to renal osteodystrophy require prompt attention. Although renal compensation and increased parathyroid hormone can maintain a normal serum phosphate level early in the course, this pathophysiologic response to hyperphosphatemia will be reflected by an increase in parathyroid hormone and alkaline phosphatase.

Uremic symptoms occur late in chronic renal failure, and include anorexia, nausea, and malaise. CNS features range from confusion, apathy, and lethargy to stupor and coma. Associated electrolyte abnormalities may precipitate seizures. More commonly, seizures are a result of untreated hypertension or hypocalcemia (especially with rapid correction of acidosis). Anemia (normochromic and normocytic from decreased renal erythropoietin synthesis) is common. Platelet dysfunction and other abnormalities of the coagulation system may be present. Bleeding—especially gastrointestinal bleeding—may be a problem. Uremic pericarditis, congestive heart failure, pulmonary edema, and hypertension may occur.

**Treatment**

**A. Management of Complications**

Treatment of chronic renal failure is primarily aimed at controlling the associated complications. Hypertension, hyperkalemia, hyperphosphatemia, acidosis, and anemia are among the early problems. Acidosis may be treated with sodium citrate solutions, as long as the added sodium will not aggravate hypertension. Sodium restriction is advisable when hypertension is present. Hyperphosphatemia is controlled by dietary restriction and dietary phosphate binders (eg, calcium carbonate). Vitamin D should be given to maintain normal serum calcium. When the BUN level exceeds approximately 50 mg/dL, or if the child is lethargic or anorexic, dietary protein should be restricted. Potassium restriction will be necessary as the GFR falls to a level where urinary output decreases sharply. Diet must be maintained to provide the child’s daily requirements.

Renal function must be monitored regularly (creatinine and BUN), and serum electrolytes, calcium, phosphorus, alkaline phosphatase, and hemoglobin and hematocrit levels monitored to guide changes in fluid and dietary management as well as dosages of phosphate binder, citrate buffer, vitamin D, blood pressure medications, and epoetin alfa. Growth failure may be treated with human recombinant growth hormone. These treatment areas require careful monitoring to minimize symptoms while the need for chronic dialysis and transplantation continues to be assessed.

Care must be taken to avoid medications that aggravate hypertension; increase the body burden of sodium, potassium, or phosphate; or increase production of BUN. Successful management relies greatly on education of the patient and family.

Attention must also be directed toward the psychosocial needs of the patient and family as they adjust to chronic illness and the eventual need for dialysis and kidney transplantation.

**B. Dialysis and Transplantation**

At present the graft survival rate for living-related kidney transplants is 90% at 1 year, 85% at 2 years, and 75% at 5 years. With cadaveric transplantation, graft survivals are 76%, 71%, and 62%, respectively. Overall, the mortality rate is 4% for recipients of living-related donors and 6.8% for recipients of cadaver organs. These percentages are affected by the increased mortality, reported to be as high as 75% in infants younger than age 1 year, primarily due to technical issues and complications of immunosuppression. A body weight of at least 15 kg is associated with a significantly improved survival rate. Adequate growth and well-being are
Hypertension in children is commonly of renal origin. It is anticipated as a complication of known renal parenchymal disease, but it may be found on routine physical examination in an otherwise normal child. Increased understanding of the roles of water and salt retention and overactivity of the renin-angiotensin system has done much to guide therapy; nevertheless, not all forms of hypertension can be explained by these two mechanisms.

The causes of renal hypertension in the newborn period include (1) congenital anomalies of the kidneys or renal vasculature, (2) obstruction of the urinary tract, (3) thrombosis of renal vasculature or kidneys, and (4) volume overload. Some instances of apparent paradoxical elevations of blood pressure have been reported in clinical situations in which chronic diuretic therapy is used, such as in bronchopulmonary dysplasia. Hypertensive infants should be examined for renal, vascular, or aortic abnormalities (e.g., thrombosis, neurofibromatosis, coarctation) as well as some endocrine disorders, including pheochromocytoma and glucocorticoid-remedial aldosteronism.

**Clinical Findings**

A child is normotensive if the average recorded systolic and diastolic blood pressures are lower than the 90th percentile for age and sex. The 90th percentile in the newborn period is approximately 85–90/55–65 mm Hg for both sexes. In the first year of life, the acceptable levels are 90–100/60–67 mm Hg. Incremental increases with growth occur, gradually approaching young adult ranges of 100–120/65–75 mm Hg in the late teens. Careful measurement of blood pressure requires correct cuff size and reliable equipment. The cuff should be wide enough to cover two thirds of the upper arm and should encircle the arm completely without an overlap in the inflatable bladder. Although an anxious child may have an elevation in blood pressure, abnormal readings must not be too hastily attributed to this cause. Repeat measurement is helpful, especially after the child has been consoled.

Routine laboratory studies include a complete blood count, urinalysis, and urine culture. Radiography and ultrasonography are used to study the anatomy of the urinary tract, the blood flow to the kidneys, and their function. A renal biopsy (which rarely reveals the cause of hypertension unless clinical evidence of renal disease is present) should always be undertaken with special care in the hypertensive patient and preferably after pressures have been controlled by therapy. Figure 22–3 presents a suggested approach to the outpatient workup of hypertension.

**Treatment**

**A. Acute Hypertensive Emergencies**

A hypertensive emergency exists when CNS signs of hypertension appear, such as papilledema or encephalopathy. Retinal hemorrhages or exudates indicate a need for prompt and effective control. In children, end-organ abnormalities secondary to hypertension commonly are not present. Treatment varies with the clinical presentation. The primary classes of useful antihypertensive drugs are (1) diuretics, (2) α- and β-adrenergic blockers, (3) angiotensin-converting enzyme inhibitors, (4) calcium channel blockers, and (5) vasodilators.

Whatever method is used to control emergent hypertension, medications for sustained control should also be initiated so that normal blood pressure will be maintained when the emergent measures are discontinued (Table 22–4). Acute elevations of blood pressure not exceeding the 95th percentile for age may be treated with oral antihypertensives, aiming for progressive improvement and control within 48 hours.

1. **Sublingual nifedipine**—This calcium channel blocker is rapid acting, and, in appropriate doses, should not result in hypotensive blood pressure levels. The liquid from a 10-mg capsule can be drawn into a syringe and the dosage approximated. The exact dosage for children who weigh less than 10–30 kg is difficult to ascertain by this method, but 5 mg is a safe starting point. Because the treatment is given for rising blood pressure, it is unlikely that the effects will be greater than desired. Larger children with malignant hypertension require 10 mg. In such cases, the capsule may simply be pierced and the medication squeezed under the patient’s tongue.

2. **Intravenous hydralazine**—This vasodilator is sometimes effective. Dosage varies according to the severity of the hypertension and should begin at about 0.15 mg/kg.
3. **Sodium nitroprusside**—In an intensive care setting, this powerful vasodilator is very effective for reducing severely elevated blood pressure. Intravenous administration of 0.5–10 mg/kg/min will reduce blood pressure in seconds; the dose must be monitored carefully. Metabolism of the drug results in thiocyanate; thus, with prolonged usage, levels of thiocyanate must be monitored, especially in renal insufficiency.

4. **Furosemide**—Administered at 1–5 mg/kg intravenously, this diuretic reduces blood volume and enhances the effectiveness of antihypertensive drugs.

**B. Sustained Hypertension**

Several choices are available (Table 22–5). A single drug such as a β-blocker (unless contraindicated, eg, in reactive airway disease) may be adequate to treat mild hypertension. Diuretics are useful to treat renal insufficiency, but the disadvantages of possible electrolyte imbalance must be considered. Single-drug therapy with an angiotensin-converting enzyme inhibitor is useful, especially because most hypertension in children is renal in origin. Calcium channel blockers are increasingly useful, and appear well tolerated in children. The use of the vasodilator type of antihypertensive drug requires concomitant...
administration of a diuretic to counter the effect of vasodilation on increasing renal sodium and water retention and a β-blocker to counter reflex tachycardia. Minoxidil, considered the most powerful of the orally administered vasodilators, can be extremely efficacious in the treatment of severe, sustained hypertension, but its effect is greatly offset by the other effects described. Hirsutism is a significant side effect. Hydralazine hydrochloride may still be the most common vasodilator in pediatric use—but, again, the necessity of using two additional drugs for maximum benefit relegates to severe situations calling for management with three or four drugs. The advice of a pediatric nephrologist should be sought.

There are many developmental, hereditary, or metabolic defects of the kidneys and collecting system. The clinical consequences include metabolic abnormalities, failure to thrive, nephrolithiasis, renal glomerular or tubular dysfunction, and chronic renal failure. Table 22–6 lists some of the major entities; discussion of the rarer conditions is beyond the scope of this book.

DISORDERS OF THE RENAL TUBULES

Three subtypes of renal tubular acidosis (RTA) are recognized: (1) the classic form, called type I or distal RTA; (2) the bicarbonate-wasting form, called type II or proximal RTA; and (3) type IV, or hyperkalemic RTA (rare in children), which is associated with hyporeninemic hypoaldosteronism. Type I and type II and their variants are encountered most frequently in children. Type III is a combination of types I and II.

Primary tubular disorders in childhood, such as glucosuria, hypouricemia, or renal glycosuria, may result from a defect in a single tubular transport pathway (see Table 22–6).

1. Distal Renal Tubular Acidosis (Type I)

The most common form of distal RTA in childhood is the hereditary form. The clinical presentation is one of failure to thrive, anorexia, vomiting, and dehydration. Hyperchloremic metabolic acidosis, hypokalemia, and a urinary pH exceeding 6.5 is found. Acidosis is more severe in the presence of a bicarbonate “leak.” This variant of distal RTA with bicarbonate wasting has been called type III but for clinical purposes need not be considered as a distinct entity. Comitant hypercalciuria may lead to rickets, nephrocalcinosis, nephrolithiasis, and renal failure.

Other situations that may be responsible for distal RTA are found in some of the entities listed in Table 22–6.
Distal RTA results from a defect in the distal nephron, in the tubular transport of hydrogen ion, or in the maintenance of a steep enough gradient for proper excretion of hydrogen ion. This defect can be accompanied by degrees of bicarbonate wasting.

The classic test for distal RTA is an acid load from \( \text{NH}_4\text{Cl} \). The test is cumbersome and can produce severe acidosis. A clinical trial of alkali administration should be used to rule out proximal (type II) RTA. The dose of alkali required to achieve a normal plasma bicarbonate concentration in patients with distal RTA is low (seldom exceeding 2–3 mEq/kg/24 h)—in contrast to that required in proximal RTA (> 10 mEq/kg/24 h). Higher doses are needed, however, if distal RTA is accompanied by bicarbonate wasting. Correction of acidosis can result in reduced complications and improved growth.

Distal RTA is usually permanent, although it sometimes occurs as a secondary complication. If the defect is not caused by a significant tubular disorder and renal damage is prevented, the prognosis is good.

2. Proximal Renal Tubular Acidosis (Type II)

Proximal RTA, the most common form of RTA in childhood, is characterized by an alkaline urine pH, loss of bicarbonate in the urine, and mildly reduced serum bicarbonate concentration. This occurs as a result of a lower than normal bicarbonate threshold, above which bicarbonate appears in the urine. Thus, urinary acidification can occur when the concentration of serum bicarbonate drops below that threshold, and bicarbonate disappears from the urine; this ability to eventually acidify the urine thus reflects normal distal tubular function.

Proximal RTA is often an isolated defect, and in the newborn can be considered an aspect of renal immaturity. Onset in infants is accompanied by failure to thrive, hyper-
chloremic acidosis, hypokalemia, and, rarely, nephrocalcinosis. Secondary forms result from reflux or obstructive uropathy or occur in association with other tubular disorders (see Table 22–6). Proximal RTA requires more than 3 mEq/kg of alkali per day to correct the acidosis. Serum bicarbonate should be monitored weekly until a level of at least 20 mEq/L is attained.

Citrate solutions (eg, Bicitra, Polycitra) are somewhat more easily tolerated than sodium bicarbonate. Bicitra contains 1 mEq/mL of Na⁺ and citrate. Polycitra contains 2 mEq/mL of citrate and 1 mEq each of Na⁺ and K⁺. The required daily dosage is divided into three doses. Potassium supplementation may be required, because the added sodium load presented to the distal tubule may exaggerate potassium losses.

The prognosis is excellent in cases of isolated defects, especially when the problem is related to renal immaturity. Alkali therapy can usually be discontinued after several months to 2 years. Growth should be normal, and the gradual increase in the serum bicarbonate level to greater than 22 mEq/L heralds the presence of a raised bicarbonate threshold in the tubules. If the defect is part of a more complex tubular abnormality (Fanconi syndrome with attendant phosphaturia, glycosuria, and aminoaciduria), the prognosis depends on the underlying disorder or syndrome.

**OCULOCEREBRORENAL SYNDROME (LOWE SYNDROME)**

Lowe syndrome results from various mutations in the ORCL1 gene, which codes for a Golgi apparatus phosphatase. Affected males have anomalies involving the eyes, brain, and kidneys. The physical stigmata and degree of mental retardation vary with the location of the mutation. In addition to congenital cataracts and buphthalmos, the typical facies includes prominent epicanthal folds, frontal prominence, and a tendency to scaphocephaly. Muscle hypotonia is a prominent finding. The renal abnormalities are of tubule function and include hypophosphatemic rickets with low serum phosphorus levels, low to normal serum calcium levels, elevated serum alkaline phosphatase levels, RTA, and aminoaciduria. Treatment includes alkali therapy, phosphate replacement, and vitamin D. Antenatal diagnosis is possible.

**CONGENITAL HYPOKALEMIC ALKALOSIS (BARTTER SYNDROME & GITELMAN SYNDROME)**

Bartter syndrome is characterized by severe hypokalemic, hypochloremic metabolic alkalosis, extremely high levels of circulating renin and aldosterone, and a paradoxic absence of hypertension. On renal biopsy, a striking juxtaglomerular hyperplasia is seen.

A neonatal form of Bartter syndrome is thought to result from mutations in two genes affecting either Na⁺–K⁺ or K⁺ transport. These patients have life-threatening episodes of fever and dehydration with hypercalciuria and early-onset nephrocalcinosis. Classic Bartter syndrome presenting in infancy with polyuria and growth retardation (but not nephrocalcinosis) is thought to result from mutations in a chloride channel gene. Gitelman syndrome occurs in older children and features episodes of muscle weakness, tetany, hypokalemia, and hypomagnesemia. These children have hypocalciuria.

Treatment with prostaglandin inhibitors and potassium-conserving diuretics (eg, amiloride combined with magnesium supplements) and potassium may be beneficial. Although the prognosis is guarded, a few patients seem to have less severe forms of the disease that are compatible with long survival times.

**CYSTINOSIS**

There are three types of cystinosis: adult, adolescent, and infantile. The adolescent type is characterized by cystine deposition, which if not treated with phosphocysteamine (Cystagon), is accompanied by the development of the renal Fanconi syndrome and varying degrees of renal failure. Growth is usually normal. The infantile type is the most common and the most severe. Characteristically, children present in the first or second year of life with Fanconi syndrome and, without the metabolic benefit of Cystagon treatment, progress to end-stage renal failure.

Cystinosis results from mutations in the CTNS gene, which codes for a cystine transporter. About 50% of patients share an identical deletion. Inheritance is autosomal recessive. Cystine is stored in cellular lysosomes in virtually all tissues. Eventually, cystine accumulation results in cell damage and cell death, particularly in the renal tubules. Renal failure between ages 6 and 12 years is common.

Whenever the diagnosis of cystinosis is suspected, slit-lamp examination of the corneas should be performed. Cystine crystal deposition causes an almost pathognomonic ground-glass “dazzle” appearance. Increased white cell cystine levels are diagnostic. Hypothyroidism is common.

Cystagon therapy is helpful in the treatment of cystinosis. Depending on the progression of chronic renal failure, management is directed toward all side effects of renal failure, with particular attention paid to the control of renal osteodystrophy. Dialysis and transplantation may be needed.

**NEPHROGENIC DIABETES INSIPIDUS**

The congenital X-linked recessive form of nephrogenic diabetes insipidus results from mutations in the vasopressin receptor, AVPR2. Autosomal (recessive and dominant) forms of nephrogenic diabetes insipidus are caused by mutations of the AQP2 gene that codes for a water channel protein, aquaporin-2. Genetic counseling and mutation testing are available.

The symptoms are polyuria, polydipsia, and failure to thrive. In some children, particularly if the solute intake is
unrestricted, adjustment to an elevated serum osmolality may develop. These children are particularly susceptible to episodes of dehydration, fever, vomiting, and convulsions.

The diagnosis can be suspected on the basis of a history of polydipsia and polyuria insensitive to the administration of vasopressin, desmopressin acetate, or lypressin. The diagnosis is confirmed by performing a vasopressin test. Carefully monitored water restriction does not increase the tubular reabsorption of water (\(\text{TcH}_2\text{O}\)) to above 3 mL/min/m\(^2\). Urine osmolality remains lower than 450 mOsm/kg, whereas serum osmolality rises and total body weight falls. Before weight reduction of more than 5% occurs or before serum osmolality exceeds 320 mOsm/kg, vasopressin should be administered. Urine concentrating ability is impaired in a number of conditions—sickle cell anemia, pyelonephritis, potassium depletion, hypercalcemia, cystinosis and other renal tubular disorders, and obstructive uropathy—and as a result of nephrotoxic drugs. Children receiving lithium treatment should be monitored for the development of nephrogenic diabetes insipidus.

In infants, it is usually best to allow water as demanded and to restrict salt. Serum sodium levels should be evaluated at intervals to avoid hyperosmolality from inadvertent water restriction. In later childhood, sodium intake should continue to be restricted to 2.0–2.5 mEq/kg/24 h. Treatment with hydrochlorothiazide is helpful, and many patients show improvement with administration of prostaglandin inhibitors such as indomethacin or tolmetin.

### Nephrolithiasis

Renal calculi in children may result from inborn errors of metabolism, such as cystine in cystinosis, glycine in hyperglycinuria, urates in Lesch–Nyhan syndrome, and oxalates in oxalosis. Stones may occur secondary to hypercalcuria in distal tubular acidosis, and large stones are quite often seen in children with spina bifida who have paralyzed lower limbs. Treatment is limited to that of the primary condition, if possible. Surgical removal of stones should be considered only for obstruction, intractable severe pain, and chronic infection.

#### 1. Cystinuria

Cystinuria, like Hartnup disease and several other disorders, is primarily an abnormality of amino acid transport across both the enteric and proximal renal tubular epithelium. There are at least three biochemical types. In the first type, the bowel transport of basic amino acids and cystine is impaired, but transport of cysteine is not impaired. In the renal tubule, basic amino acids are again rejected by the tubule, but cystine absorption appears to be normal. The reason for cystinuria remains obscure. Heterozygous individuals have no aminoaciduria. The second type is similar to the first except that heterozygous individuals excrete excess cystine and lysine in the urine, and cystine transport in the bowel is normal. In the third type, only the nephron is involved. The only clinical manifestations are related to stone formation: ureteral colic, dysuria, hematuria, proteinuria, and secondary urinary tract infection (UTI). Urinary excretion of cystine, lysine, arginine, and ornithine is increased.

The most reliable way to prevent stone formation is to maintain a constantly high free-water clearance. This involves generous fluid intake. Alkalization of the urine is helpful. If these measures do not prevent significant renal lithiasis, the use of tiopronin (Thiola) is recommended.

### 2. Primary Hyperoxaluria

Oxalate in humans is derived from the oxidative deamination of glycite to glyoxylate, from the serine-glycolate pathway, and from ascorbic acid. At least two enzymatic blocks have been described. Type I is a deficiency of liver-specific peroxisomal alanine–glyoxylate aminotransferase. Type II is glyoxylate reductase deficiency.

Excess oxalate combines with calcium to form insoluble deposits in the kidneys, lungs, and other tissues, beginning during childhood. The joints are occasionally involved, but the main effect is on the kidneys, where progressive oxalate deposition leads to fibrosis and eventual renal failure.

Pyrdoxine supplementation and a low-oxalate diet have been tried as therapy, but the overall prognosis is poor, and most patients succumb to uremia by early adulthood. Renal transplantation is not very successful because of destruction of the transplant kidney. However, encouraging results have been obtained with concomitant liver transplantation, correcting the metabolic defect.

Hyperoxaluria may also be a consequence of severe ileal disease or ileal resection.

### Urinary Tract Infections

It is estimated that 8% of girls and 2% of boys will acquire UTIs in childhood. Girls older than age 6 months have UTIs far more commonly than boys, whereas uncircumcised boys younger than 3 months of age have more UTIs than girls. Circumcision reduces the risk of UTI in boys. The density of distal urethral and periurethral bacterial colonization with uropathogenic bacteria correlates with the risk of UTI in children. Most UTIs are ascending infections. Specific adhesins present on the fimbria of uropathogenic bacteria allow colonization of the uroepithelium in the urethra and bladder and increase the likelihood of UTI.

#### Pathogenesis

Dysfunctional voiding, which is uncoordinated relaxation of the urethral sphincter during voiding, leads to incomplete emptying of the bladder, increasing the risk of bacterial colonization. Similarly, any condition that interferes with complete emptying of the bladder, such as constipation or
neurogenic bladder, increases the risk of UTI. Poor perineal hygiene, structural abnormalities of the urinary tract, catheterization, instrumentation of the urinary tract, and sexual activity increase the risk as well.

The inflammatory response to pyelonephritis may produce renal parenchymal scars. Such scars in infancy and childhood may contribute to hypertension, renal disease, and renal failure later in life. The organisms most commonly responsible for UTI are fecal flora, most commonly E. coli (> 85%), Klebsiella, Proteus, other gram-negative bacteria, and, less frequently, Enterococcus or coagulase-negative staphylococci.

**Clinical Findings**

**A. Symptoms and Signs**

Newborns and infants with UTI have nonspecific signs, including fever, hypothermia, jaundice, poor feeding, irritability, vomiting, failure to thrive, and sepsis. Strong, foul-smelling or cloudy urine may be noted. Preschool children may have abdominal or flank pain, vomiting, fever, urinary frequency, dysuria, urgency, or enuresis. School-aged children commonly have classic signs of cystitis (frequency, dysuria, and urgency) or pyelonephritis (fever, vomiting, and flank pain). Costovertebral tenderness is unusual in young children, but may be demonstrated by school-aged children. Physical examination should include attention to blood pressure determination, abdominal examination, and a genitourinary examination. Urethritis, poor perineal hygiene, herpes simplex virus, or other genitourinary infections may be apparent on examination.

**B. Laboratory Findings**

Collection of urine for urinalysis and culture is difficult in children due to frequent contamination of the sample. In toilet-trained, cooperative, older children, a midstream, clean-catch method is satisfactory. Although cleaning of the perineum does not improve specimen quality, straddling of the toilet to separate the labia in girls, retraction of the foreskin in boys, and collecting midstream urine significantly reduce contamination. In infants and young children, bladder catheterization or suprapubic collection is necessary in most cases to avoid contaminated samples. Bagged urine specimens are helpful only if negative.

Screening urinalysis indicates pyuria (> 5 WBCs/high-power field) in most children with UTI, but many children with pyuria do not have UTI. White cells from the urethra or vagina may be present in urine or may be in the urine because of a systemic infection. The leukocyte esterase test correlates well with pyuria, but has a similar false-positive rate. The detection of urinary nitrite by dipstick is highly correlated with enteric organisms being cultured from urine. Most young children (70%) with UTI have negative nitrite tests. They empty their bladders frequently, and it requires several hours for bacteria to convert ingested nitrates to nitrite in the bladder. The sensitivity of nitrite detection is highest on a first morning void. Gram stain of unspun urine correlates well with culture recovery of 10^5 colony-forming units (cfu)/mL or more, but this test is frequently unavailable outside the hospital.

The gold standard for diagnosis remains the culture of a properly collected urine specimen. Specimens that are not immediately cultured should be refrigerated and kept cold during transport. Any growth is considered significant from a suprapubic culture. Quantitative recovery of 10^5 cfu/mL or more is considered significant on clean-catch specimens, and 10^4–10^5 is considered significant on catheterized specimens. Usually the recovery of multiple organisms indicates contamination, but some contaminated specimens yield only a single species.

Asymptomatic bacteriuria is detected in 0.5–1.0% of children who are screened with urine culture. Asymptomatic bacteriuria is believed to represent colonization of the urinary tract with nonuropathogenic bacteria. Treatment may increase the risk of symptomatic UTI by eliminating non-pathogenic colonization. Screening urine cultures in nonsymptomatic children are, therefore, generally discouraged. Repeated urine cultures are often helpful in differentiating asymptomatic bacteriuria from contamination of the culture versus true UTI.

Urinary function during UTI should be assessed by measurement of BUN and serum creatinine concentration.

**C. Imaging**

Because congenital urologic abnormalities increase the risk of UTI, radiologic evaluation of first UTI has been routinely recommended. These recommendations usually include routine ultrasound of the kidneys and voiding cystourethrogram (VCUG). Vesicoureteral reflux (VUR) is a congenital abnormality present in about 1% of the population. VUR is graded using the international scale (I—reflux into ureter; II—reflux to the kidney; III—reflux to kidney with dilation of ureter only; IV—reflux with dilation of ureter and mild blunting of renal calyces; V—reflux with dilation of ureter and blunting of renal calyces). Reflux is detected in 30–50% of children 1 year of age and younger. The natural history of reflux is to improve, and 80% of reflux of grades I, II, or III will resolve or significantly improve within 3 years following detection.

VCUG should be done selectively on children with a first UTI. Children with a suspected urologic abnormality due to weak stream, dribbling, or perineal abnormalities should be studied with VCUG. Boys with a first UTI should be studied to detect posterior urethral valves, an important congenital abnormality that requires surgery. Children older than 3 years of age who are otherwise healthy and growing well usually can be followed clinically and do not need VCUG for a first UTI. The yield in sexually active teenagers is also very low.

Ultrasonographic examination of kidneys should be done in children with acute pyelonephritis who have not improved after 3–5 days of antimicrobial treatment adjusted for the
susceptibility of the organism. The examination is done to detect renal or perirenal abscesses or obstruction of the kidney.

**Treatment**

**A. Antibiotic Therapy**

Management of UTI is influenced by clinical assessment. Very young children (younger than 3 months) and children with dehydration, toxicity, or sepsis should be admitted to the hospital and treated with parenteral antimicrobials. Older infants and children who are not seriously ill can be treated as outpatients. Initial antimicrobial therapy is based on prior history of infection and antimicrobial use, as well as location of the infection in the urinary tract.

Uncomplicated cystitis can be treated with amoxicillin, trimethoprim–sulfamethoxazole, or a first-generation cephalosporin. These antimicrobials are concentrated in the lower urinary tract, and high cure rates are common. There are significant differences in the rates of antimicrobial resistance, so knowledge of the rates in the local community is important. More seriously ill children are initially treated parenterally with a third-generation cephalosporin or an aminoglycoside. The initial antimicrobial choice is adjusted after culture and susceptibility are known. The recommended duration of antimicrobial therapy for uncomplicated cystitis is 7–10 days. For sexually mature teenagers with cystitis, fluoroquinolones such as ciprofloxacin and levofloxacin for 3 days are effective and cost-effective. Short-course therapy of cystitis is not recommended in children, because differentiating upper and lower tract disease may be difficult, and higher failure rates are reported in most studies of short-course therapy.

Acute pyelonephritis is usually treated for 10 days. The duration of parenteral therapy in uncomplicated pyelonephritis is not well defined, but most children can complete therapy orally once symptomatic improvement has occurred. A repeat urine culture 24–48 hours after beginning therapy is not needed if the child is improving and doing well.

**B. Follow-Up**

Children with UTI should be followed with screening urinalysis 1 and 2 months after resolution of UTI. Dipstick nitrate determination can be used at home by parents on first morning voided urine in children with frequently recurring UTI.

**C. Prophylactic Antimicrobials**

Selected children with frequently recurring UTI may benefit from prophylactic antimicrobials. In children with high-grade VUR, prophylactic antimicrobials may be beneficial in reducing UTI, as an alternative to surgical correction, or in the interval prior to surgical therapy. Many experts recommend surgical correction of higher-grade reflux, particularly grade V. Trimethoprim–sulfamethoxazole and nitrofurantoin are approved for prophylaxis. The use of broader-spectrum antimicrobials leads to colonization and infection with resistant strains.

Children with dysfunctional voiding generally do not benefit from prophylactic antimicrobials; rather, addressing the underlying dysfunctional voiding is most important.

NEUROLOGIC ASSESSMENT & NEURODIAGNOSTIC PROCEDURES

HISTORY & EXAMINATION

A general physical examination (albeit sometimes truncated) and an age-appropriate developmental assessment are part of every neurologic visit. Information provided in several earlier chapters is relevant in this context. Chapter 2 delineates age-appropriate developmental landmarks (see Tables 2–1 and 2–2); the Denver II schedule (see Figure 2–12) is helpful, especially in infancy. Growth and head circumference charts (you should measure the head) are also included in Chapter 2. Details of the standard pediatric history and physical examination are presented in Chapter 8. Expected newborn-infant reflexes and automations and other examination suggestions pertinent to that age group are included in Chapter 1.

Table 23–1 outlines components of the neurologic examination. Examination of a frightened or wary infant can begin on the mother’s lap. Playing games will engage a toddler or preschooler: retrieving, casting a ball, stacking blocks, hopping, jogging, counting, and drawing (circles, lines) can reduce anxiety and exhibit fine and gross motor coordination, balance, and handedness. On occasion beyond preschool age, describing a picture, drawing, writing, calculating, and spelling will aid in assessing speech and intelligence.

Emphasis (or fine tuning) of both history and physical examination strongly depends on the chief complaint. Insidious developmental delay or weakness might demand detailed exploration of pregnancy, family, and social history; developmental landmarks; and general physical, motor, and speech achievements. Headaches or seizures in an older child warrant more emphasis on precise details preceding and during these events.

LUMBAR PUNCTURE

Spinal fluid is usually obtained by inserting a small-gauge needle (eg, No. 22) through the L3–L4 intervertebral space into the thecal sac while the patient is lying on his or her side. After an opening pressure is measured, a small amount of fluid is removed most frequently to examine for evidence of infection or inflammation (Table 23–2). Fluid is sent for red and white cell counts, for determination of the concentrations of protein and glucose, and for viral and bacterial cultures. In some cases, additional information is obtained with special staining techniques for mycobacteria and fungus. Additional fluid may be sent for polymerase chain reaction (PCR) testing for specific viral agents, antibody titer determinations, cytopathologic study, lactate and pyruvate concentrations, and amino acid and neurotransmitter analysis. Lumbar puncture is imperative when bacterial meningitis is suspected. Caution must be exercised, however, when signs of increased intracranial pressure (eg, papilledema) or focal neurologic signs are present that might indicate a substantial risk of precipitating tentorial or tonsillar herniation.

ELECTROENCEPHALOGRAPHY

Electroencephalography (EEG), a widely used noninvasive electrophysiologic method for recording cerebral activity, has its greatest clinical applicability in the study of seizure disorders. EEG is particularly helpful in showing epileptiform activity. Sometimes the findings are diagnostic, as in the hypsarrhythmia EEG of infantile spasms or the prolonged generalized 3/s spike-wave of absence seizures.

EEG is also used in the evaluation of tumors, cerebrovascular accidents, neurodegenerative diseases, and other neurologic disorders causing brain dysfunction. Recordings over a 24-hour period or all-night recordings are invaluable in the diagnosis of sleep disturbances and narcolepsy. EEG with telemetry or simultaneous monitoring of behavior on videotape has great usefulness in selected cases. The EEG can be helpful in determining a possible cause or mechanism of coma and whether subclinical seizures are contributing to the coma, and can help determine whether coma is irreversible and brain death has occurred.
The limitations of EEG are considerable. In most cases, the duration of the actual tracing is about 45 minutes and reflects only surface cortical function. Many drugs, especially barbiturates and benzodiazepines, may cause artifact on the tracing and may confuse interpretation. Moreover, about 15% of nonepileptic individuals, especially children, may have an abnormal EEG. EEG findings such as those occasionally seen in migraine, learning disabilities, or behavior disorders are often nonspecific and do not reflect structural brain damage.

Computed tomography (CT) scans, evoked potentials, positron emission tomography (PET), regional cerebral blood flow studies, single-photon emission computed tomography (SPECT), and magnetic resonance imaging (MRI) supplement the EEG as a diagnostic and prognostic tool.

The reproducible and quantifiable results obtained from brainstem auditory, pattern-shift visual, and short-latency somatosensory evoked potentials (see section on short-latency somatosensory evoked potentials) indicate the level of function of the relevant sensory pathway or system and identify the site of anatomic disruption. Although results of these tests alone are usually not diagnostic, the tests are noninvasive, sensitive, objective, and relatively inexpensive extensions of the clinical neurologic examination. Because the auditory and somatosensory tests and one type of visual test are completely passive, requiring only that the patient remain still, they are particularly useful in the evaluation of neonates, young children, and patients unable to cooperate. Knowledge of normal values and experience in testing are mandatory.

### Brainstem Auditory Evoked Potentials

A brief auditory stimulus (click) of varying intensity and frequency is delivered to the ear to activate the auditory

*CSF-IgG index = CSF IgG/serum IgG ÷ CSF albumin/serum albumin.*

*Many studies document pitfalls in using these ratios due to WBC lysis. Clinical judgment and repeat lumbar punctures may be necessary to rule out meningitis in this situation.*

*CSF WBC (predicted) = CSF RBC × (blood WBC/blood RBC). O:P ratio = observed CSF WBC ÷ predicted CSF WBC. Also, do WBC:RBC ratio. If O:P ratio ≤ 0.01, and WBC:RBC ratio ≤ 1:100, meningitis is absent. nerve (nerve VIII) and sequentially activate the cochlear nucleus, tracts and nuclei of the lateral lemniscus, and inferior colliculus. Thus this technique assesses hearing and function of the brainstem auditory tracts.

Hearing in the neonate or uncooperative patient can be assessed objectively, making the technique particularly useful in high-risk infants and in mentally retarded or autistic patients. Because high doses of anesthetic agents or barbiturates do not seriously affect results, the test is used to assess and monitor brainstem function of surgical patients (in the operating room) and those in hypoxic-ischemic coma or coma following head injury. Absence of evoked potential waves beyond the first wave from the auditory nerve usually signifies brain death. Brainstem auditory evoked potentials are also useful in the early evaluation of diseases affecting myelin such as the leukodystrophies and multiple sclerosis, although auditory evoked potentials are less valuable than visual evoked potentials in the evaluation of multiple sclerosis. Intrinsic brainstem gliomas and brainstem encephalitis (eg, enterovirus 71) can also be evaluated with auditory evoked potentials. They are sometimes useful in evaluation of hereditary ataxias, Wilson disease, and other degenerative disorders of the brainstem.

**Pattern-Shift Visual Evoked Potentials**

The preferred stimulus is a shift (reversal) of a checkerboard pattern, and the response is a single wave (called P-100) generated in the striate and parastriate visual cortex. The absolute latency of P-100 (time from stimulus to wave peak) and the difference in latency between the two eyes are sensitive indicators of disease. The amplitude of response is affected by any process resulting in poor fixation on the stimulus screen or affecting visual acuity. Ability to focus on a checkerboard pattern is necessary. An LED (light-emitting diode) in goggles, or bright flash stimulus can be used in younger and uncooperative children, but the norms are less standardized. This is a less sensitive whole retina (rather than only macula) stimulation that may give normal results in a child who is legally blind.

Clinical applications of the test include detection and monitoring of strabismus (eg, in amblyopia ex anopsia), optic neuritis, and lesions near the optic nerve and chiasm such as optic gliomas and craniopharyngiomas. Degenerative and immunologic diseases that affect visual transmission may be detected early and followed by serial evaluations. Examples of such diseases include adrenoleukodystrophy, Pelizaeus-Merzbacher disease, some spinocerebellar degenerations, sarcoidosis, and even multiple sclerosis. Flash visual evoked potentials are used to monitor function during surgery on the eyes or optic nerve, to assess cortical or hysterial blindness, and to evaluate patients with photosensitive epilepsy, who may have exaggerated responses.

**Short-Latency Somatosensory Evoked Potentials**

Responses are commonly produced by electrical stimulation of peripheral sensory nerves, because this evokes potentials of greatest amplitude and clarity. Finger tapping and muscle stretching may also be used to stimulate somatosensory potentials. The function of this test is similar to that of the auditory test in closely correlating waveforms with function of the sensory pathways and permitting localization of conduction defects.

Short-latency somatosensory evoked potentials are used in the assessment of a wide variety of lesions of the peripheral nerve, root, spinal cord, and central nervous system (CNS) following trauma, neuropathies (eg, in diabetes mellitus or Guillain-Barré syndrome), myelodysplasias, Arnold-Chiari malformation, and achondroplasia. The procedure is often performed on an outpatient basis. One method is stimulation of the median nerve at the wrist with small (nonpainful) electrical shocks and recording of responses from the brachial plexus above the clavicle, the neck (cervical cord), and the opposite scalp area overlying the sensorimotor cortex. After stimulation from the knee (peroneal nerve) or ankle (tibial nerve), impulses are recorded from the lower lumbar spinal cord, cervical cord, and sensorimotor cortex. Such potentials are used to monitor spinal cord sensory functioning during surgery for scoliosis, myelodysplasias, tumors, and other lesions of the spinal cord or its blood vessels. The technique is also used in leukodystrophies involving peripheral nerves, in multiple sclerosis, and in the evaluation of hysteria and malingering (anesthetic limbs). In the diagnosis of coma and brain death, somatosensory evoked potentials supplement the results of auditory evoked potentials.

**Sedation for Procedures**

Oral chloral hydrate, 30–60 mg/kg per dose, is safest. Many radiology departments, however, use intravenously administered agents because of the risks of vomiting and aspiration. One favorite is pentobarbital, 6 mg/kg for children weighing less than 15 kg and 5 mg/kg for larger children (up to a maximum of 200 mg) given intramuscularly or rectally (at least 20 minutes before a procedure), or 2–4 mg/kg given intravenously. Equipment to support blood pressure and respiration must be available. This dosage usually achieves sedation for up to 2 hours. If, however, sedation is inadequate 30 minutes after injection, and if the child’s condition permits a second dose of pentobarbital, 2 mg/kg is given. Midazolam, 0.1 mg/kg IV or 0.2 mg/kg intranasally, is gaining popularity for brief procedures (eg, Botox injection).

**Computed Tomography**

CT scanning consists of a series of cross-sectional (axial) roentgenograms. Radiation exposure is approximately the same as that from a skull radiographic series. CT images record variations in tissue density and can be viewed on a television screen as the scan is being done, and later examined on films. CT scanning is of high sensitivity (88–96% of
lesions larger than 1–2 cm can be seen) but low specificity (tumor, infection, or infarct may look the same). Sedation is usually not needed. CT scan is occasionally repeated after intravenous injection of iodized contrast for enhancement, which reflects the vascularity of a lesion or its surrounding tissues. Most CT scans do not require enhancement. Lastly, CT angiography (CTA; no injection is needed) is often “more available” in an acute stroke evaluation, gives excellent cross-sectional views of major arteries, and may identify the site of an acute thrombosis. Radiation dose is a disadvantage of all CT scanning.

**Magnetic Resonance Imaging**

MRI is a noninvasive technique that uses the magnetic properties of certain nuclei to produce diagnostically useful signals. Currently the technique is based on detecting the response (resonance) of hydrogen proton nuclei to applied radiofrequency electromagnetic radiation. These nuclei are abundant in the body and more sensitive to MRI than other nuclei. The strength of MRI signals varies with the relationship of water to protein and the amount of lipid in the tissue. The MRI image displayed provides high-resolution contrast of soft tissues. MRI can provide information about the histologic, physiologic, and biochemical status of tissues in addition to gross anatomic data. Sedation is necessary in children younger than age 6 years to avoid any movement artefact.

MRI has been used to delineate brain tumors, edema, ischemic and hemorrhagic lesions, hydrocephalus, vascular disorders, inflammatory and infectious lesions, and degenerative processes. MRI can be used to study myelination and demyelination, and through the demonstration of changes in relaxation time, metabolic disorders of the brain, muscles, and glands. Because bone causes no artifact in the images, the posterior fossa and its contents can be studied far better using MRI than with CT scans. Even blood vessels and the cranial nerves can be imaged. In contrast, the lesser ability of MRI to detect calcification limits its usefulness in the investigation of calcified lesions such as craniopharyngioma and leptomeningeal angiomatosis.

Magnetic resonance angiography (MRA) or venography (MRV) is a noninvasive (no arterial or venous puncture or dye injection) technique to show large extra- and intracranial blood vessels. It often replaces the more hazardous intrarterial injection angiogram. An advantage over CTA (see previous section) is the lack of radiation exposure.

Perfusion imaging involving a paramagnetic contrast agent is used in stroke patients to evaluate brain ischemic penumbra. Similarly, diffusion imaging (measuring random motion of water molecules) may show reduced diffusion in areas of cytotoxic edema, and is useful in acute strokes and toxic or metabolic brain injuries. The area of involvement often exceeds the T1 hypodense or T2 hyperdense stroke area, and this penumbra possibly reflects recoverable tissue injury as compared with totally infarcted tissue, cell death, or apoptosis (programmed cell death) in the center of the stroke.

Another new MRI technique, proton MR spectroscopy, measures signals of increased cellular activity and oxidative metabolism; neuronal acetyl aspartate, phosphocreatinine, and phosphomonoester are increased. Ratios are often calculated to choline and P_i (inorganic phosphate). Increased lactate (anaerobic metabolism), choline, and creatinine, reflecting increased cell surface area—as in gliosis or scarring—can be assessed in a chosen voxel or tiny area of interest. An epileptic focus in the medial temporal lobe is an example; an active seizure site might show increased metabolism. Sclerosis and gliosis (“scar”) would show the converse.

Functional MRI can be performed at the same time as an ongoing regular MRI. Blood oxygenation changes in an area of interest (eg, an area of language acquisition) during rest and then during a verbal work paradigm can identify and lateralize the language cortex. A change in the ratio of oxyhemoglobin to deoxyhemoglobin results in a detectable MRI signal.

**Positron Emission Tomography**

PET is an imaging technique that measures the metabolic rate at a given site by CT scanning. For measurement of local cerebral metabolism, the radiolabeled substrate most frequently used has been intravenously administered fluoro-deoxyglucose. Gray matter and white matter are clearly distinguishable; the skull and air- or fluid-filled cavities are least active metabolically.

PET has been used to study the cerebral metabolism of neonates and brain activation by visual or auditory stimuli. Pathologic states that have been studied include epilepsy, brain infarcts, brain tumors, and dementias. This functional test of brain metabolism is useful in preoperative evaluation for epilepsy surgery. The epileptogenic zone will often be hypermetabolic during seizures and hypoactive during the time between seizures. The information from PET scan complements EEG and MRI findings to aid in the decision about tissue removal. In infants with infantile spasms, PET scan has occasionally detected focal lesions, thereby leading to successful surgical removal. Clinical application is limited by the cost of the procedure and the clinician’s need for access to a nearby cyclotron for preparation of the radiopharmaceuticals.

**Ultrasonography**

Ultrasonography offers a pictorial display of the varying densities of tissues in a given anatomic region by recording the echoes of ultrasonic waves reflected from it. These waves, modulated by pulsations, are introduced into the tissue by means of a piezoelectric transducer. The many advantages of ultrasonography include the ability to assess a structure and its positioning quickly with easily portable equipment, without ionizing radiation, and at about one fourth the cost of CT scanning. Sedation is usually not necessary, and the procedure can be repeated as often as needed without risk to the patient. In brain imaging, B-mode and real-time sector
scanners are usually used, permitting excellent detail in the coronal and sagittal planes. Contiguous structures can be studied by a continuous sweep and reviewed on videotape.

Ultrasoundography has been used for in-utero diagnosis of hydrocephalus and other anomalies. In neonates, the thin skull and the open anterior fontanelle have facilitated imaging of the brain, and ultrasonography is used to screen and follow infants of less than 32 weeks’ gestation or weighing less than 1500 g for intracranial hemorrhage. Other uses in neonates include detection of hydrocephalus, major brain and spine malformations, and calcifications from intrauterine infection with cytomegalovirus (CMV) or Toxoplasma. In skilled hands, sonography of the neonatal spine can be used as a screening test for anomalies at the lumbosacral level.

**Cerebral Angiography**

Arteriography remains a useful procedure in the diagnosis of many cerebrovascular disorders, particularly in cerebrovascular accidents or in potentially operable vascular malformations. In some brain tumors, arteriography may be necessary to define the precise location or vascular bed, to differentiate among tumors, or to distinguish tumor from abscess or infarction. Noninvasive CT, MRI, and MRA scans can diagnose many cases of static or flowing blood disorders (eg, sinus thromboses). If necessary, the more risky invasive arteriography is usually done via femoral artery-aorta catheterization.

**Myelography**

Radiographic examination of the spine may be indicated in cases of spinal cord tumors, myelitis, or various forms of spinal dysraphism and in the rare instance of herniated disks in children. MRI has largely replaced sonography, CT, and myelography for examination of the spinal cord.

---

**REFERENCES**

intubation. Breathing and adequate air exchange can be assessed by auscultation; hand bag respiratory assistance with oxygen may be needed. Circulation must be ensured by assessing pulse and blood pressure. An intravenous line is always necessary. Fluids, plasma, blood, or even a dopamine drip (1–20 mcg/kg/min) may be required in cases of hypotension. An extremely hypothermic or febrile child may require vigorous cooling or warming to save life. The assessment of vital signs may signal the diagnosis. Slow, insufficient respirations suggest poisoning by hypnotic drugs; apnea may indicate diphenoxylate hydrochloride poisoning. Rapid, deep respirations suggest acidosis, possibly metabolic, as with diabetic coma; toxic, such as that due to aspirin; or neurogenic, as in Reye syndrome. Hyperthermia may indicate infection or heat stroke; hypothermia may indicate cold exposure, ethanol poisoning, or hypoglycemia (especially in infancy).

The signs of impending brain herniation are another priority of the initial assessment. Bradycardia, high blood pressure, irregular breathing, increased extensor tone, and third nerve palsy with the eye deviated outward and the pupil dilated are possible signs of impending temporal lobe or brainstem herniation. These signs suggest a need for slight hyperventilation, reducing cerebral edema, prompt neurosurgical consultation, and possibly, in an infant with a bulging fontanelle, subdural or ventricular tap (or both). Initial intravenous fluids should contain glucose until further assessment disproves hypoglycemia as a cause.

A history obtained from parents or witnesses is desirable. Sometimes the only history will be obtained from ambulance attendants. An important point is whether the child is known to have a chronic illness, such as diabetes, hemophilia, epilepsy, or cystic fibrosis. Recent acute illness raises the possibility of coma caused by viral or bacterial meningitis. Trauma is a common cause of coma. Lack of a history of trauma, especially in infants, does not rule it out. Nonaccidental trauma or a fall not witnessed by caregivers may have occurred. In coma of unknown cause, poisoning is always a possibility. Absence of a history of ingestion of a toxic substance or of medication in the home does not rule out poisoning as a cause.

Often the history is obtained concurrently with a brief pediatric and neurologic screening examination. After the assessment of vital signs, the general examination proceeds with a trauma assessment. Palpation of the head and fontanelle, inspection of the ears for infection or hemorrhage, and a careful examination for neck stiffness are indicated. If circumstances suggest head or neck trauma, the head and neck must be immobilized so that any fracture or dislocation will not be aggravated. The skin must be inspected for petechiae or purpura that might suggest bacteremia, infection, bleeding disorder, or traumatic bruising. Examination of the chest, abdomen, and limbs is important to exclude enclosed hemorrhage or traumatic fractures.

Neurologic examination quantifies the stimulus response and depth of coma, such as responsiveness to verbal or painful stimuli. Examination of the pupils, optic fundi, and eye movements is important. Are the eye movements spontaneous, or is it necessary to do the doll’s-eye maneuver (rotating the head rapidly to see whether the eyes follow)? Motor and sensory examinations assess reflex asymmetries, Babinski sign, and evidence of spontaneous posturing or posturing induced by noxious stimuli (eg, decorticate or decerebrate posturing).

If the cause of the coma is not obvious, emergency laboratory tests must be obtained. Table 23–4 lists some of the causes of coma in children. Most comas (90%) in children have a medical (versus structural) cause. Infection is a common cause (30%). An immediate blood glucose (or Dextrostix), complete blood count, urine obtained by catheterization if necessary, pH and electrolytes (including bicarbonate), serum urea nitrogen, and aspartate aminotransferase are initial screens. Urine, blood, and even gastric contents must be saved for toxin screen if the underlying cause is not obvious. Blood culture and lumbar puncture often are necessary to rule out CNS infection. Papilledema is a relative contraindication to lumbar puncture. Occasionally, blood culture is obtained, antibiotics started, and imaging study of the brain done prior to a diagnostic lumbar puncture. If meningitis is suspected and a lumbar puncture is delayed or believed to be hazardous, antibiotics should be started and the diagnostic lumbar punc-
ture done later. Tests that are helpful in obscure cases of coma include oxygen and carbon dioxide partial pressures, ammonia levels, serum and urine osmolality, porphyrins, lead levels, and urine and serum amino acids and urine organic acids. If head trauma or increased pressure is suspected, an emergency CT scan or MRI is necessary. Bone windows on the former study or skull radiographs can be done at the same sitting. The absence of skull fracture does not rule out coma caused by closed head trauma. Injury that results from shaking a child is one example. In a child with an open fontanelle, a real-time ultrasound may be transiently substituted for the other, more definitive imaging studies if there is good local expertise. Treatment of head injury associated with coma is discussed in detail in Chapter 11.

Rarely, an emergency EEG aids in diagnosing the cause of coma. Nonconvulsive status epilepticus or a focal finding seen

AGN, acute glomerulonephritis; SIADH, syndrome of inappropriate antidiuretic hormone.
with herpes encephalitis (periodic lateralized epileptiform discharges) and focal slowing as seen with stroke or cerebritis are cases in which the EEG might be helpful. The EEG also may correlate with the stage of coma and add prognostic information.

B. General Measures

Vital signs must be monitored and maintained. Most emergency departments and intensive care units have flow sheets that provide space for repeated monitoring of the coma; a coma scale can be a useful tool for this purpose. The patient’s response to vocal or painful stimuli and orientation to time, place, and situation are monitored. Posture and movements of the limbs, either spontaneously or in response to pain, are serially noted. Pupillary size, equality, and reaction to light, and movement of the eyes to the doll’s-eye maneuver or ice-water caloric tests should be recorded. Intravenous fluids can be tailored to the situation, as for treatment of acidosis, shock, or hypovolemia. Nasogastric suction is initially important. The bladder should be catheterized for monitoring urine output and for urinalysis.

C. Seizure Management

An EEG should be ordered if seizures are suspected. If obvious motor seizures have occurred, treatment for status epilepticus is given with intravenous drugs (see later section on Seizure Disorders). If brainstem herniation or increased pressure is possible, intracranial monitoring may be necessary. This procedure is described in more detail in Chapter 13. Initial treatment of impending herniation includes keeping the patient’s head up (15–30 degrees) and providing slight hyperventilation. The use of mannitol, diuretics, corticosteroids, and drainage of cerebrospinal fluid (CSF) are more heroic measures covered in detail in Chapter 13.

Prognosis

About 50% of children with nontraumatic causes of coma have a good outcome. In studies of adults assessed on admission or within the first days after the onset of coma, an analysis of multiple variables was most helpful in assessing prognosis. Abnormal neuro-opthalmologic signs (eg, the absence of pupillary reaction or of eye movement in response to the doll’s-eye maneuver or ice water caloric testing and the absence of corneal responses) were unfavorable. Delay in the return of motor responses, tone, or eye opening was also unfavorable. In children, the assessment done on admission is about as predictive as one done in the succeeding days. Approximately two thirds of outcomes can be successfully predicted at an early stage on the basis of coma severity, extraocular movements, pupillary reactions, motor patterns, blood pressure, temperature, and seizure type. Other characteristics, such as the need for assisted respiration, the presence of increased intracranial pressure, and the duration of coma, are not significantly predictive. Published reports suggest that an anoxic (in contrast to traumatic, metabolic, or toxic) coma, such as that caused by near drowning, has a much grimmer outlook.

BRAIN DEATH

Many medical and law associations have endorsed the following definition of death: An individual who has sustained either (1) irreversible cessation of circulatory and respiratory functions or (2) irreversible cessation of all functions of the entire brain, including the brainstem, is dead. A determination of death must be made in accordance with accepted medical standards. Representatives from several pediatric and neurologic associations have endorsed the Guidelines for the Determination of Brain Death in Children. The criteria in full-term infants (ie, those born at greater than 38 weeks’ gestation) were applicable 1 week after the neurologic insult. Difficulties in assessing premature infants and full-term infants shortly after birth were acknowledged.

Prerequisites

In assessment of brain death, the history is important. The physician must determine proximate causes to make sure no remediable or reversible conditions are present. Examples of such causes are metabolic conditions, toxic agents, sedative-hypnotic drugs, surgically remediable conditions, hypothermia, and paralytic agents.

Physical Examination Criteria

(See also Chapter 13.) The following criteria are those established by the Task Force on Brain Death in Children:

1. Coexistence of coma and apnea: The patient must exhibit complete loss of consciousness, vocalization, and volitional activity.

2. Absence of brainstem function: As defined by the following: (a) Midposition or fully dilated pupils that do not respond to light; drugs may influence and invalidate pupillary assessment. (b) Absence of spontaneous eye movements and those induced by side-to-side passive head movements (oculocephalic reflex) and ice water instillation in the external auditory canal (ice water caloric test; intact tympanic membranes must be documented). (c) Absence of movement of bulbar musculature, including facial and oropharyngeal muscles; the corneal, gag, cough, sucking, and rooting reflexes are absent. (d) Absence of respiratory movements when the patient is off the respirator; apnea testing using standardized methods can be performed but is done after other criteria are met.

3. Temperature and blood pressure: The patient must not be significantly hypothermic or hypotensive for age.

4. Tone: Tone is flaccid, and spontaneous or induced movements are absent, excluding spinal cord events such as reflex withdrawal or spinal myelocclus.

5. General examination findings: The examination should remain consistent with brain death throughout the observation and testing period.
Confirmation

Apnea testing should be carried out at a partial carbon dioxide pressure level greater than 60 mm Hg, and with normal oxygenation maintained throughout the test period. This level may be reached 3–15 minutes after taking the patient off the respirator. The recommended observation period to confirm brain death (repeated examinations) is 12–24 hours (longer in infants); reversible causes must be ruled out. If an irreversible cause is documented, laboratory testing is not essential. Helpful tests to support the clinical assertion of brain death include EEG and angiography. Electroencephalographic silence on EEG should persist for 30 minutes, and drug concentrations must be sufficient to suppress EEG activity. Absence of intracranial arterial blood flow can be confirmed by carotid angiography and cerebral radionuclide angiography. Persistence of dural sinus flow does not invalidate the diagnosis of brain death.

Cerebral evoked potentials, intracranial blood pulsations on ultrasound, and xenon-enhanced CT have not been sufficiently studied to be considered definitive in the diagnosis of brain death. In rare cases, preserved intracranial perfusion in the presence of EEG silence has been documented, and the converse has also been reported.

General Considerations

A seizure is a sudden, transient disturbance of brain function, manifested by involuntary motor, sensory, autonomic, or psychic phenomena, alone or in any combination, often accompanied by alteration or loss of consciousness. Seizures can be caused by any factor that disturbs brain function. They may occur after a metabolic, traumatic, anoxic, or infectious insult to the brain (classified as remote symptomatic seizures), or spontaneously without prior known CNS insult.

Repeated seizures without evident acute symptomatic cause (eg, fever) are defined as epilepsy. Epilepsy occurs most often in individuals at the extremes of the life span. The incidence is highest in the newborn period, and higher in childhood than in later life, with another peak in the elderly. Prevalence flattens out after age 10–15 years. The chance of having a second seizure after an initial unprovoked episode in a child is about 50%. The risk of recurrence after a second unprovoked seizure is 85%. Sixty-five to 70% of children with epilepsy will achieve seizure remission with appropriate medication. Epilepsy with childhood onset remits in about 50% of children.

Classification

The International League Against Epilepsy (ILAE) has established classifications of seizures and epilepsy syndromes. Seizures are classified as either as partial (with localized onset) or generalized, involving the whole brain. Seizures and epilepsy syndromes may be partial at onset and then secondarily generalize (partial seizures with secondary generalization), or generalized from the onset.

Epilepsy syndromes are defined by the nature of the seizures (ie, localized vs generalized), age of onset, EEG findings, and other clinical factors. Epilepsy is classified as symptomatic (the cause is identified or presumed and may be due to a remote CNS injury), cryptogenic (undetermined etiology, presumably symptomatic and often due to congenital CNS abnormalities), or idiopathic (often genetic). In general, symptomatic and cryptogenic epilepsy have their onset early in life. Idiopathic (genetic) epilepsy syndromes are usually age specific, occurring at any age from early infancy to adolescence, depending on the specific syndrome. The specific epilepsy syndrome is helpful in defining prognosis, with idiopathic epilepsy more likely to be controlled and eventually remit than symptomatic epilepsy.

1. Seizures & Epilepsy in Childhood

Classifying the seizure is necessary for accurate diagnosis, which will determine the nature of further evaluation and treatment and help in prognostication (Tables 23–5 and 23–6).
<table>
<thead>
<tr>
<th>Seizure Type</th>
<th>Age at Onset</th>
<th>Clinical Manifestations</th>
<th>Causative Factors</th>
<th>EEG Pattern</th>
<th>Other Diagnostic Studies</th>
<th>Treatment and Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Neonatal seizures</td>
<td>Birth-2 wk</td>
<td>Often subtle; sudden limpness or tonic posturing, brief apnea, and cyanosis; odd cry; eyes rolling up; blinking or mouthing or chewing movements; nystagmus, twitchiness or clonic movements (focal, multifocal, or generalized). Some seizures are nonepileptic: decerebrate, or other posturings, release from forebrain inhibition. Poor response to drugs.</td>
<td>Neurologic insults (hypoxia/ischemia; intracranial hemorrhage) present more in first 3 d or after 8th day; metabolic disturbances alone between 3rd and 8th days; hypoglycemia, hypocalcemia, hyper- and hyponatremia. Drug withdrawal. Pyridoxine dependency. CNS infections. Structural abnormalities.</td>
<td>May correlate poorly with clinical seizures. Focal spikes or slow rhythms; multifocal discharges. Electroclinical dissociation may occur: EEG-electrical seizure without clinical manifestations and vice versa.</td>
<td>Lumbar puncture; CSF PCR for herpes, enterovirus; serum Ca(^{2+}), PO(_4)(^{3–}), glucose, Mg(^{2+}); BUN, amino acid screen, blood ammonia, organic acid screen, TORCHS IgM. Ultrasound or CT/MRI for suspected intracranial hemorrhage and structural abnormalities.</td>
<td>Phenobarbital, IV or IM; if seizures not controlled, add phenytoin IV (loading dose 20 mg/kg each). Diazepam, 0.3 mg/kg. Recent experience with levetiracetam and topiramate. Treat underlying disorder. Seizures due to brain damage often resistant to anticonvulsants. When cause in doubt, stop protein feedings until enzyme deficiencies of urea cycle or amino acid metabolism ruled out.</td>
</tr>
<tr>
<td>West syndrome (infantile spasms)</td>
<td>3-18 mo</td>
<td>Sudden, usually but not always symmetrical adduction or flexion of limbs with flexion of head and trunk; or abduction and extensor movements (similar to Moro reflex). Occur in clusters. Associated irritability and regression in development.</td>
<td>Symptomatic in approximately two thirds. Acquired CNS injury in approximately one third; biochemical, infectious, degenerative in approximately one third; cryptogenic in approximately one third. With early onset, pyridoxine dependency, inherited metabolic disorders. Tuberous sclerosis in 5–10%. TORCHS, homeobox gene mutations.</td>
<td>Hypsarrhythmia; chaotic high-voltage slow waves or random spikes (90%); other abnormalities in 10%. Rarely normal at onset. EEG normalization early in course usually correlates with reduction of seizures; not helpful prognostically regarding mental development.</td>
<td>Funduscopic and skin examination, trial of pyridoxine. Amino and organic acid screen. Chronic inflammatory disease. TORCHS screen, CT, or MRI scan should be done to (1) establish definite diagnosis, (2) aid in genetic counseling. Occasionally, surgical resection of cortical malformation useful.</td>
<td>ACTH gel (40 U/d to 150 U/m(^2)) IM once daily. Vigabatrin, especially if tuberous sclerosis. B(_6) (pyridoxine) trial. In resistant cases, zonisamide, valproic acid, topiramate, lamotrigine, ketogenic diet. Mental retardation of varying degree in 90% of cases.</td>
</tr>
<tr>
<td>Febrile convulsions</td>
<td>3 mo-5 y (maximum 6-18 mo); most common childhood seizure (incidence 2%)</td>
<td>Usually generalized seizures, &lt; 15 min; rarely focal in onset. May lead to status epilepticus. Recurrence risk of second febrile seizure 30% (50% if under 1 y of age); recurrence risk is same after status epilepticus.</td>
<td>Non-neurologic febrile illness (temperature rises to 39°C or higher); Risk factors: positive family history, day care, slow development, prolonged neonatal hospitalization.</td>
<td>Normal interictal EEG, especially when obtained 8-10 d after seizure.</td>
<td>Lumbar puncture in infants or whenever suspicion of meningitis exists.</td>
<td>Treat underlying illness, fever. Diazepam orally, 0.3-0.5 mg/kg, divided 3 times daily during illness may be considered. Diastat rectally for prolonged (&gt; 5 min) seizure. Prophylaxis with phenobarbital or valproic acid rarely needed.</td>
</tr>
<tr>
<td>Diagnosis</td>
<td>Age</td>
<td>Description</td>
<td>Cause</td>
<td>EEG Findings</td>
<td>Treatment</td>
<td>Other Considerations</td>
</tr>
<tr>
<td>-----------</td>
<td>-----</td>
<td>-------------</td>
<td>-------</td>
<td>--------------</td>
<td>-----------</td>
<td>---------------------</td>
</tr>
<tr>
<td>Childhood absence epilepsy</td>
<td>3–12 y</td>
<td>Lapses of consciousness or vacant stares, lasting about 3–10 s, often in clusters. Automatisms of face and hands; tonic activity in 30–45%. Often confused with complex partial seizures but no aura or postictal confusion.</td>
<td>Unknown. Genetic component. Abnormal thalamocortical circuitry.</td>
<td>3/s bilaterally synchronous, symmetrical, high-voltage spikes and waves. EEG normalization correlates closely with control of seizures.</td>
<td>Hyperventilation often provokes attacks. Imaging studies rarely of value.</td>
<td>Valproic acid, lamotrigine, or ethosuximide. In resistant cases, zonisamide, topiramate, levetiracetam, acetazolamide, ketogenic diet.</td>
</tr>
<tr>
<td>Juvenile absence epilepsy</td>
<td>10–15 y</td>
<td>Absence seizures less frequent than in childhood absence epilepsy. May have greater risk of convulsive seizures.</td>
<td>Unknown (idiopathic), possibly genetic.</td>
<td>3-Hz spike wave and atypical generalized discharges.</td>
<td>Not always triggered by hyperventilation.</td>
<td>Same as childhood absence epilepsy but may be more difficult to treat successfully.</td>
</tr>
<tr>
<td>Simple partial or focal seizures (motor/sensory/jacksonian)</td>
<td>Any age</td>
<td>Seizure may involve any part of body; may spread in fixed pattern (Jacksonian march), becoming generalized. In children, epileptogenic focus often “shifts,” and epileptic manifestations may change concomitantly.</td>
<td>Often unknown; birth trauma, inflammatory process, vascular accidents, meningitis or meningoencephalitis, etc. If seizures are coupled with new or progressive neurological deficits, a structural lesion (eg, brain tumor) is likely. If epilepsy partialis continua (simple partial status epilepticus), Rasmussen syndrome is likely.</td>
<td>EEG may be normal; focal spikes or slow waves in appropriate cortical region; sometimes diffusely abnormal or even normal. “Rolando spikes” (centrotemporal spikes) are typical. Possibly genetic.</td>
<td>If seizures are difficult to control or progressive deficits occur, neuroradiographic diagnostic studies, particularly MRI brain scan, are imperative.</td>
<td>Carbamazepine, oxcarbazepine, phenytoin, lamotrigine, gabapentin, topiramate, levetiracetam, and zonisamide. Valproic acid useful adjunct.</td>
</tr>
<tr>
<td>Cryptogenic generalized epilepsies of early childhood, including Lennox-Gastaut syndrome and myoclonic-astatic epilepsy (Doose syndrome)</td>
<td>Any time in childhood (usually 2–7 y)</td>
<td>Mixed seizures dependent on particular syndrome, including tonic, myoclonic (shocklike violent contractions of one or more muscle groups, singly or irregularly repetitive); atonic (“drop attacks”) and atypical absence with episodes of absence status epilepticus.</td>
<td>Multiple causes, usually resulting in diffuse neuronal damage. History of West syndrome; prenatal or perinatal brain damage; viral meningoencephalitis; CNS degenerative disorders; structural cerebral abnormalities (eg, migration abnormalities). Doose syndrome may be genetic.</td>
<td>Atypical slow (1–2.5 Hz) spike-wave complexes and bursts of high-voltage generalized spikes, often with diffusely slow background frequencies. Electro-decremental and fast spikes during sleep.</td>
<td>As dictated by index of suspicion. Consider inherited metabolic disorders, neuronal ceroid lipofuscinosis, others. Skin or conjunctival biopsy for electron microscopy, MRI scan, WBC lysosomal enzymes, nerve conduction studies if degenerative disease suspected.</td>
<td>Difficult to treat. Topiramate, ethosuximide, felbamate, levetiracetam, zonisamide, valproate, clonazepam, ketogenic diet, vagus nerve stimulation. Avoid phenytoin, carbamazepine, oxcarbazepine, gabapentin.</td>
</tr>
</tbody>

<table>
<thead>
<tr>
<th>Seizure Type</th>
<th>Age at Onset</th>
<th>Clinical Manifestations</th>
<th>Causative Factors</th>
<th>EEG Pattern</th>
<th>Other Diagnostic Studies</th>
<th>Treatment and Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Complex partial seizures</td>
<td>Any age</td>
<td>Aura may be a sensation of fear, epigastric discomfort, odd smell or taste (usually unpleasant), visual or auditory hallucination. Aura and seizure stereotyped for each patient. Seizure may consist of vague stare; facial, tongue, or swallowing movements and throaty sounds; or various complex automatisms. Usually brief, 15–90 s, followed by confusion. History of aura and of automatisms involving more than face and hands establish diagnosis.</td>
<td>As above. Temporal lobes especially sensitive to hypoxia; seizure may be a sequela of birth trauma, febrile convulsions, viral encephalitis, especially herpes. Remediable other causes are small cryptic tumors or vascular malformations. May be genetic.</td>
<td>As above, but occurring in temporal lobe and its connections (eg, frontotemporal, temporoparietal, temporop-occipital regions).</td>
<td>MRI when structural lesions suspected. PCR of CSF in acute febrile situation for herpes or enteroviral encephalitis. SPECT, PET scan, video EEG monitoring when epilepsy surgery considered.</td>
<td>Carbamazepine, phenytoin. More than one drug may be necessary. Valproic acid may be useful. In cases uncontrolled by drugs and where a primary epileptogenic focus is identifiable, excision of anterior third of temporal lobe. Oxcarbazepine, topiramate, lamotrigine, levetiracetam, and zonisamide.</td>
</tr>
<tr>
<td>Benign epilepsy of childhood with centrotemporal spikes</td>
<td>5–16 y</td>
<td>Partial motor or generalized seizures. Similar seizure patterns may be observed in patients with focal cortical lesions. Usually nocturnal simple partial seizures of face, tongue, hand.</td>
<td>Seizure history or abnormal EEG findings in relatives of 40% of affected probands and 18–20% of parents and siblings, suggesting transmission by a single autosomal dominant gene, possibly with age-dependent penetrance.</td>
<td>Centrolateral spikes or sharp waves (“rolandic discharges”) appearing paroxysmally against a normal EEG background.</td>
<td>Seldom need CT or MRI scan.</td>
<td>Carbamazepine or other agent. (See complex partial seizures.) Often no medication is necessary, especially if seizure is exclusively nocturnal and infrequent. Lamotrigine, topiramate, levetiracetam, zonisamide.</td>
</tr>
<tr>
<td>Juvenile myoclonic epilepsy (of Janz)</td>
<td>Late childhood and adolescence, peaking at 13 y</td>
<td>Mild myoclonic jerks of neck and shoulder flexor muscles after awakening. Intelligence usually normal. Often absence seizures, and generalized tonic-clonic seizures as well.</td>
<td>40% of relatives have myoclonias, especially in females; 15% have the abnormal EEG pattern with clinical attacks.</td>
<td>Intercitial EEG shows variety of spike-and-wave sequences or 4–6-hz multipike-and-wave complexes (“fast spikes”).</td>
<td>If course is unfavorable, differentiate from progressive myoclonic syndromes by appropriate biopsies (muscles, liver, etc).</td>
<td>Valproic acid, lamotrigine, topiramate, levetiracetam, zonisamide.</td>
</tr>
<tr>
<td>Generalized tonic-clonic seizures (grand mal) (GTCS)</td>
<td>Any age</td>
<td>Loss of consciousness; tonic-clonic movements, often preceded by vague aura or cry. Incontinence in 15%. Prolonged confusion; sleep. Often mixed with or masking other seizure patterns.</td>
<td>Often unknown. Genetic component. May be seen with metabolic disturbances, trauma, infection, intoxication, degenerative disorders, brain tumors.</td>
<td>Bilaterally synchronous, symmetrical multiple high-voltage spikes, spikes-waves (eg, 3/5). EEG often normal in those younger than age 4 y. Focal spikes may become “secondarily generalized.”</td>

Clinical Findings

A. History, Symptoms, and Signs

Seizures are clinical events; the key to diagnosis is the clinical history. Not all paroxysmal events are epileptic. A description of seizure onset is important in determining if there is localized onset (partial or focal seizure). Events prior to, during, and after the seizure need to be described (although observers often recall little except generalized convulsive activity because of its dramatic appearance). An aura (actually a simple partial seizure) may precede the clinically apparent seizure and indicates focal onset. The patient may describe a feeling of fear, numbness or tingling in the fingers, or bright lights in one visual field. The specific symptoms may help define the location of seizure onset (e.g., déjà vu suggests temporal lobe onset). Often, the child does not recall or cannot define the aura though the family may note alterations in behavior at the onset.

Details of the seizure’s semiology can help determine the seizure type and, if partial, the site of onset. Did the patient become extremely pale before falling? Was the patient able to respond to queries during the episode? Was the patient unconscious or was there just impaired awareness? Did the patient fall stiffly or gradually slump to the floor? Was there an injury? How long did the tonic stiffening or clonic jerking last? Where in the body did the clonic activity take place? Postictal states can be helpful in diagnosis. After complex partial and generalized convulsive seizures, postictal sleep typically occurs, but postictal changes are not seen after generalized absence seizures. Was there loss of speech after the seizure (suggesting left temporal lobe seizure) or was the patient able to respond and speak in short order? The parent may report lateralized motor activity (e.g., the child’s eyes may deviate to one side or the child may experience dystonic posturing of a limb). Motor activity without impaired awareness supports the diagnosis of simple partial seizures. Impaired awareness and automatisms define the event as a complex partial seizure.

In contrast, primary generalized seizures manifest with acute loss of consciousness, usually with generalized motor activity. Tonic posturing, tonic–clonic activity or myoclonus (spasms) may occur. In children with generalized absence seizures, behavioral arrest may be associated with automatisms such as blinking, chewing, or hand movements, making it difficult to differentiate between absence seizures and partial seizures.

Description of the semiology of the event may help determine if the child experienced an epileptic seizure or a nonepileptic event mimicking or misinterpreted as an epileptic seizure. Frequently the child presenting with a presumed first seizure has experienced unrecognized seizures before the event that brings the child to medical attention. In particular, partial and absence seizures may not be recognized except in retrospect. Thus careful questioning regarding prior events is important in the child being evaluated for new onset of seizures.

B. Diagnostic Evaluation

The extent and urgency of the diagnostic evaluation is determined, in general, by the child’s age, the severity and type of seizure, whether the child is ill or injured, and the clinician’s suspicion about the underlying cause. Seizures in early infancy are often symptomatic. Therefore, the younger the child, the more extensive must be the diagnostic assessment (Table 23–7).
It is generally accepted that every child with new onset of unprovoked seizures should be evaluated with an EEG, although this need not be done emergently. An EEG is very unlikely to yield clinically useful information in the child with a febrile seizure. Other diagnostic studies should be used selectively.

Metabolic abnormalities are seldom found in the well child with seizures. Unless there is a high clinical suspicion of serious medical conditions (e.g., uremia, hyponatremia, hypocalcemia, etc.), “routine” laboratory tests rarely yield clinically significant information. Special studies may be necessary in circumstances that suggest an acute systemic etiology for a seizure, for example, in the presence of apparent renal failure, sepsis, or substance abuse.

Emergent imaging of the brain is usually not necessary in the absence evidence of trauma or of acute abnormalities on examination. Nonurgent MRI should be performed in any child with a significant cognitive or motor impairment, or abnormalities on neurologic examination of unknown etiology, a seizure of partial (focal) onset, or an EEG that does not represent benign partial epilepsy of childhood or primary generalized epilepsy, and should be seriously considered in infants younger than 1 year of age.

The child with a simple febrile seizure or an unprovoked generalized seizure with normal examination and normal EEG often will not require imaging. Clinically significant abnormalities rarely are found on imaging of children with new onset of idiopathic epilepsy syndromes such as benign focal epilepsy of childhood (BECTS or rolandic epilepsy) and absence epilepsy with a normal neurologic examination and diagnostic EEG. Conversely, in children with symptomatic epileptic syndromes such as infantile spasms and Lennox-Gastaut syndrome, MRI (the preferred study) will be abnormal in as many as 60–80% of patients. Evidence of localization related epilepsy is an indication for MRI of the brain. Imaging is not necessary in children with BECTS, but the yield with other focal seizures is 15–30%, with findings supportive of the diagnosis (e.g., focal cortical dysplasia) and useful in defining the prognosis. Other indications for MRI scan include difficulty in controlling seizures, progressive

neurologic findings on serial examinations, worsening focal findings on the EEG, or other evidence of progressive neurologic dysfunction, even in the instance where a prior imaging scan was normal.

C. Electroencephalography

Appropriate use of EEG requires awareness of its limitations as well as its utility. The limitations of EEG even with epilepsy, for which it is most useful, are considerable. A routine EEG captures electrical activity during a very short period of time, usually 30–40 minutes. Thus it is useful primarily for defining interictal activity (except for the fortuitous recording of a clinical seizure or in the case of childhood absence epilepsy). A seizure is a clinical phenomenon; an EEG showing epileptiform activity may confirm and even extend the clinical diagnosis, but it is only occasionally diagnostic.

1. Diagnostic value—The greatest value of the EEG in convulsive disorders is to help classify seizure types and epilepsy syndromes. This can aid in prognostication and in selecting appropriate therapy (see Table 23–5). Hypomotor seizures (absence and complex partial seizures) are sometimes difficult to distinguish. The differing EEG patterns of these seizures will then prove most helpful. The presence of a mixed seizure EEG pattern in a child with clinically generalized convulsive seizures or only focal seizures may lead to identification of specific epilepsy syndromes and help the clinician select anticonvulsants effective for the seizure types identified by the EEG. Similarly, the EEG may help in diagnosing seizures in a young infant with minimal or atypical clinical manifestations; it may show hypsarrhythmia (high-amplitude spikes and slow waves with a chaotic background) in West syndrome (infantile spasms) or the 1–4/s slow spike-wave pattern of the Lennox-Gastaut syndrome. The EEG may show focal slowing that, if constant, particularly when corresponding focal seizure manifestations and abnormal neurologic findings are present, will alert the physician to the presence of a structural lesion. In this case, brain imaging may establish the cause and help determine further investigation and treatment.

The EEG need not be abnormal in a child with epilepsy. Normal EEGs are seen following a first generalized seizure in one third of children younger than age 4 years. The initial EEG is normal in about 20% of older epileptic children and in about 10% of epileptic adults. These percentages are reduced when serial tracings are obtained. Focal spikes and generalized spike-wave discharges are seen in 30% of close nonepileptic relatives of patients with epilepsy.

2. Prognostic value—A normal EEG following a first convulsion suggests (but does not guarantee) a favorable prognosis. Hypsarrhythmia or slow spike and wave patterns support the diagnosis of West syndrome and Lennox-Gastaut syndrome respectively. Both are expressions of diffuse brain dysfunction (epileptic encephalopathy) and are generally of grave significance. Central-temporal (rolandic spikes) and occipital spike wave activity (occipital paroxysms) are the EEG correlates of idiopathic focal epilepsies of childhood.

Following successful treatment, abnormal EEGs may become normal and may aid in the decision to discontinue medications. The normalization of the EEG in childhood absence epilepsy confirms the efficacy of treatment. Normalization can also be seen in infants with West syndrome who have been successfully treated and, less commonly, in children with epileptic encephalopathies.

Electroencephalography should be repeated when the severity and frequency of seizures increase despite adequate anticonvulsant therapy, when the clinical seizure pattern changes significantly, or when progressive neurologic deficits develop. Emergence of new focal or diffuse slowing may indicate a progressive lesion or neurodegenerative disorder.

The EEG may be helpful in determining when to discontinue anticonvulsant therapy. The presence or absence of epileptiform activity on the EEG prior to withdrawal of anticonvulsants after a seizure-free period of 2 years on medications has been shown to correlate with the degree of risk of seizure recurrence.

Differential Diagnosis

It is extremely important to be accurate in the diagnosis of epilepsy and not to make the diagnosis without ample proof. To the layperson, epilepsy often has connotations of brain damage and limitation of activity. A person so diagnosed may be excluded from certain occupations in later life. It is often very difficult to change an inaccurate diagnosis of many years’ standing.

Misinterpretation of behaviors in children is the most common reason for misdiagnosis. Psychogenic seizures are much less common in children than in adults but must be considered even in the young or cognitively impaired child. The most commonly misinterpreted behaviors are inattention in school-aged children with attention disorders, stereotypes in children with autistic spectrum disorder, sleep-related movements, habit movements such as head-banging and so-called infantile masturbation (sometimes referred to as gratification movements), and gastroesophageal reflux in very young (often impaired) infants.

Some of the common nonepileptic events that mimic seizure disorder are listed in Table 23–8.

Complications & Sequelae

A. Psychosocial Impact

Emotional disturbances, especially depression but also including anxiety, anger, and feelings of guilt and inadequacy, often occur in the patient as well as the parents of a child with epilepsy. Actual or perceived stigma as well as issues regarding “disclosure” are common. There may be an increased risk of suicide in people with epilepsy. Schools often limit activities of children with epilepsy inappropriately and stigmatize children by these limitations.
**Table 23-8. Nonepileptic paroxysmal events.**

<table>
<thead>
<tr>
<th>Nonepileptic Paroxysmal Events</th>
<th>Nonepileptic Paroxysmal Events</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Breath-holding attacks (cyanotic and pallid)</strong></td>
<td><strong>Gastroesophageal reflux (Sandifer syndrome)</strong></td>
</tr>
<tr>
<td>Cyanotic: Age 6 mo–3 y. Always precipitated by trauma and fright. Cyanosis; sometimes stiffening, tonic (or jerking-clonic) convolution (anoxic seizure). Patient may sleep following attack. Family history positive in 30%. Electroencephalogram (EEG) normal. Treatment is interpretation and reassurance.</td>
<td>Seen more commonly in children with cerebral palsy or brain damage; reflux of acid gastric contents may cause pain that cannot be described by child. Unusual posturing (dystonic or other) of head and neck or trunk may occur, an apparent attempt to stretch the esophagus or close the opening. There is no loss of consciousness, but eye rolling, apnea, and occasional vomiting may simulate a seizure. An upper gastrointestinal series, cine of swallowing, sometimes even an EEG (normal during episode) may be necessary to distinguish from seizures.</td>
</tr>
<tr>
<td>Pallid: No external precipitant (perhaps internal pain, cramp, or fear?). Pallor may be followed by seizure (anoxic-ischemic). Vagally (heart-slowing) mediated, like adult syncope. EEG normal; may see cardiac slowing with vagal stimulation (cold cloth on face) during EEG. May be seen in children with cyanotic spells as well.</td>
<td><strong>Infantile masturbation</strong></td>
</tr>
<tr>
<td>Tics (Tourette syndrome)</td>
<td>Rarely in infants, repetitive rocking or rubbing motions may simulate seizures. Infant may look out of contact, be poorly responsive to environment, and have autonomic expressions (eg, perspiration, dilated pupils) that may be confused with seizures. Observation by a skilled individual, sometimes even in a hospital setting, may be necessary to distinguish from seizures. EEG is normal between or during attacks. Interpretation and reassurance are the only necessary treatment.</td>
</tr>
<tr>
<td>Simple or complex stereotyped jerks or movements, coughs, grunts, sniffs. Worse at repose or with stress. May be suppressed during physician visit. Family history often positive for tics or for obsessive compulsive disorder. Diagnosis is clinical. MRI and EEG are negative. Medications may benefit.</td>
<td><strong>Conversion reaction/pseudoseizures</strong></td>
</tr>
<tr>
<td>Parasomnias (Night terrors, sleep talking, walking, “sit-ups”)</td>
<td>Up to 50% of patients with pseudoseizures have epilepsy. Episodes may involve writhing, intercourse-like movements, tonic movements, bizarre jerking and thrashing, or even apparently sudden unresponsiveness. Often, there is ongoing psychological trauma. Often, but not invariably, children are developmentally delayed. Spells must often be seen or recorded on videotape in a controlled situation to distinguish from epilepsy but are sometimes so bizarre they are easily differentiated. A normal EEG during a spell is a key diagnostic feature. Sometimes, pseudoseizures can be precipitated by suggestion with injection of normal saline in a controlled situation. Combativeness is common; self-injury and incontinence, rare.</td>
</tr>
<tr>
<td>Ages 3–10 y. Usually occur in first sleep cycle (30–90 min after going to sleep), with crying, screaming, and autonomic discharge (pupils dilated, perspiring, etc). May last only a few minutes or be more prolonged. Child goes back to sleep and has no recall of event next day. Sleep studies (polysomnogram and EEG) are normal. Sleep talking and walking and short “sit-ups” in bed are fragmentary arousals. If a spell is recorded, EEG shows arousal from deep sleep, but behavior seems wakeful. Child needs to be protected from injury and gradually settled down and taken back to bed. Medications may be considered in rare instances.</td>
<td><strong>Temper tantrums and rage attacks</strong></td>
</tr>
<tr>
<td>Nightmares</td>
<td>Sometimes confused with epilepsy. Child is often amnesic or at least claims amnesia for events during spell. Attacks are usually precipitated by frustration or anger, often directed either verbally or physically, and subside with behavior modification and isolation. EEGs are generally normal but unfortunately seldom obtained during an attack. Anterior temporal leads may help rule out temporal or lateral frontal abnormalities, the latter sometimes seen in partial complex seizures. Improvement of attacks with psychotherapy, milieu therapy, or behavioral modification helps rule out epilepsy.</td>
</tr>
<tr>
<td>Nightmares or vivid dreams occur in subsequent cycles of sleep, often in early morning hours, and generally are partially recalled the next day. The bizarre and frightening behavior may sometimes be confused with complex partial seizures but occurs during REM (rapid eye movement) sleep, whereas epilepsy usually does not. In extreme or difficult cases, an all-night sleep EEG may help differentiate seizures from nightmares.</td>
<td><strong>Benign paroxysmal vertigo</strong></td>
</tr>
<tr>
<td>Migraine</td>
<td>Brief attacks of vertigo in which child often appears frightened and pale and clutches parent. Attacks last 5–30 s. Sometimes, nystagmus is identified. There is no loss of consciousness. Usually, child is well and returns to play immediately afterward. Attacks may occur in clusters, then disappear for months. Attacks are usually seen in infants and preschoolers aged 2–5 y. EEG is normal. If caloric tests can be obtained (often very difficult in this age group), abnormalities with hypofunction of one side are sometimes seen. Medications are usually not desirable or necessary.</td>
</tr>
<tr>
<td>One migraine variant can be associated with an acute confusional state. Usual migraine prodrome of spots before the eyes, dizziness, visual field defects, and then agitated confusion may be present. History of other, more typical migraine with severe headache and vomiting but without confusion may aid in diagnosis. Severe headache with vomiting as child comes out of spell may aid in distinguishing the attack from epilepsy. Other seizure manifestations are practically never seen (eg, tonic-clonic movements, falling, complete loss of consciousness). EEG in migraine is usually normal and seldom has epileptiform abnormalities often seen in patients with epilepsy. Migraine and epilepsy are sometimes linked: migraine-caused ischemia on the surface sometimes leads to later epilepsy. Are both channelopathies?</td>
<td><strong>Staring spells</strong></td>
</tr>
<tr>
<td>Benign nocturnal myoclonus</td>
<td>Teachers often make referral for absence or petit mal seizures in children who stare or seem preoccupied at school. Helpful in the history is the lack of these spells at home (eg, before breakfast, a common time for absence seizures). Lack of other epilepsy in child or family history often is helpful. These children sometimes have difficulties with school and cognitive or learning disabilities. Child can generally be brought out of spell by a firm command. EEG is sometimes necessary to confirm that absence seizures are not occurring. A 24-hour ambulatory EEG to record attacks during child’s everyday school activities is occasionally necessary.</td>
</tr>
<tr>
<td>Common in infants and may last even up to school age. Focal or generalized jerks (the latter also called hypnic or sleep jerks) may persist from onset of sleep on and off all night. A video record for physician review can aid in diagnosis. EEG taken during jerks is normal, proving that these jerks are not epilepsy. Treatment is reassurance.</td>
<td></td>
</tr>
</tbody>
</table>
Epilepsy with onset in childhood has an impact on adult function. Adults with early onset of epilepsy are less likely to complete high school, have less adequate employment, and are less likely to marry. Persistent epilepsy results in significant dependence; even when epilepsy is successfully treated, patients with long-standing epilepsy often do not become independent.

Rarely, psychosis may be seen in patients with epilepsy; usually in older children and adults.

### B. Cognitive Delay

There remains considerable debate about the impact of seizures and epilepsy on cognition. Clearly, epileptic encephalopathy (ie, regression in cognitive ability and development associated with uncontrolled seizures) does occur, particularly in young children with catastrophic epilepsies such as West syndrome and Lennox-Gastaut syndrome. It is less clear whether persistent partial seizures have an impact on development. It is even less likely that interictal epileptiform activity contributes to cognitive impairment. However, continuous epileptiform activity in sleep is associated with Landau-Kleffner syndrome (acquired epileptic aphasia).

Pseudodementia may occur in children with poorly controlled epilepsy because their seizures interfere with their learning. Depression is a common cause of impaired cognitive function in children with epilepsy. Anticonvulsants are less likely to cause such interference at usual therapeutic doses. However, all antiepileptic drugs carry some risk for adverse impact on cognition. Phenobarbital, in particular, but also topiramate, valproate, and others, may be implicated.

Mental retardation and autistic spectrum disorders may be part of the same pathologic process that causes the seizures but may occasionally be worsened when seizures are frequent, prolonged, and accompanied by hypoxia.

### C. Injury and Death

Physical injuries, especially lacerations of the forehead and chin, are frequent in astatic or akinetic seizures (so-called drop attacks), necessitating protective headgear. In all other seizure disorders in childhood, injuries as a direct result of an attack are not as common although drowning, injuries related to working in kitchens, and falls from heights remain a potential risk for all children with active epilepsy. It is therefore extremely important to stress “seizure precautions,” in particular, water safety.

Sudden unexpected death with epilepsy (SUDEP) is a very rare event. The greatest fear of a parent of a child with new-onset of epilepsy is the possibility of death or brain injury. Although children with epilepsy have an increased risk of death, SUDEP is very rare (1–2:10,000 patient-years). Nearly all of the mortality in children with epilepsy is related to the underlying neurologic disorder, not the seizures. The greatest risk for SUDEP is in children with medically uncontrolled epilepsy, especially with symptomatic epilepsy (associated with identifiable CNS etiology). Normal children with epilepsy do not have an increased risk of death compared with the general population. There is no current proven strategy to prevent SUDEP. The mechanism for SUDEP is unclear but is probably most commonly related to postictal respiratory insufficiency. Occasionally the cause is a cardiac arrhythmia induced by a seizure. Vigorous attempts to control intractable seizure disorders remain the most important approach. Identifying life-threatening disorders (eg, identifying patients with cardiac arrhythmias, especially prolonged QT syndrome) as the cause of misdiagnosed epilepsy is clearly of utmost importance.

#### Treatment

The ideal treatment of seizures is the correction of specific causes. However, even when a biochemical disorder, a tumor, meningitis, or another specific cause is being treated, anticonvulsant drugs are often still required.

### A. First Aid

Caregivers should be instructed to protect the patient against self-injury. Turning the child to the side is useful for preventing aspiration. Thrusting a spoon handle, tongue depressor or finger into the clenched mouth of a convulsing patient or trying to restrain tonic-clonic movements may cause worse injuries than a bitten tongue or bruised limb. Parents are often concerned that cyanosis will occur during generalized convulsive seizures but it is rare for clinically significant hypoxia to occur. Mouth-to-mouth resuscitation is rarely necessary and is unlikely to be effective.

For prolonged seizures (those lasting over 5 minutes), rectal diazepam gel (Diastat) may be administered to prevent the development of status epilepticus. Diastat has proven to be safe even when administered by nonmedical professionals, including teachers and day-care providers, when appropriately instructed.

### B. Antiepileptic Drug (AED) Therapy

1. **Drug selection**—Treat with the drug appropriate to the clinical situation, as outlined in Table 23–5.

2. **Treatment strategy**—The child with a single seizure has a 50% chance of recurrence. Thus, it is usually not necessary to initiate AED therapy until the diagnosis of epilepsy is established, that is, there is a second seizure. The seizure type and epilepsy syndrome as well as potential side-effects will determine which drug to initiate (see Table 23–5). Start with one drug in moderate dosage and increase the dosage until seizures are controlled. If seizures are not controlled on the maximal tolerated dosage of one major AED, gradually switch to another before using two-drug therapy. Polytherapy (ie, the use of more than two medications concurrently) is rarely sufficiently effective to warrant the considerable risk of adverse side effects from the synergistic impact of multiple medications.

Dosages and usually target serum levels of commonly prescribed AEDs are listed in Table 23–9. Individual variations...

(continued)
must be expected, both in tolerance and efficacy. The therapeutic range may also vary somewhat with the method used to determine levels, and published levels are not always reflective of clinical efficacy and tolerability.

3. Counseling—Advise the parents and the patient that the prolonged use of AEDs will not produce significant or permanent mental slowing (although the underlying cause of the seizures might) and that prevention of seizures for 1–2 years substantially reduces the chances of recurrence. Advise them also that AEDs are given to prevent further seizures and that they should be taken as prescribed. Changes in medications or dosages should not be made without the physician’s knowledge. Unsupervised sudden withdrawal of AEDs may precipitate severe seizures or even status epilepticus. Medications must be kept where they cannot be ingested by small children or suicidal patients.

Older children should be encouraged to manage their medications on their own, but some degree of supervision by parents is often necessary to guarantee adherence to treatment regimens. Medications are invariably missed on occasions. Making up a single dose is reasonable, but making up multiple doses should be discouraged.

4. Follow-up—Regular follow-up evaluations of the patient are appropriate at intervals that depend on the degree of control, underlying cause of the seizures, and toxic properties of the AEDs used. Blood counts and liver function tests (aspartate aminotransferase; AST) are often obtained periodically in patients taking the older AEDs, such as valproate, phenytoin, and carbamazepine. Periodic neurologic reevaluation is important. Repeat EEGs are useful for confirming seizure-freedom in children with absence epilepsy and West syndrome but otherwise are usually not useful as measures of medication efficacy.

5. Long-term management and discontinuation of treatment—AEDs should be continued until the patient is free of seizures for at least 1–2 years. In about 75% of patients, seizures may not recur. Variables such as younger age at onset, normal EEG, idiopathic etiology and ease of controlling seizures carry a favorable prognosis, whereas symptomatic etiology, later onset, continued epileptiform EEG, difficulty in establishing initial control of the seizures, polytherapy, generalized tonic-clonic or myoclonic seizures, as well as an abnormal neurologic examination are associated with a higher risk of recurrence. Most AEDs (with the exception of barbiturates and clonazepam) can be withdrawn over 6–8 weeks. There does not appear to be an advantage to slower withdrawal.

Recurrent seizures affect up to 25% of children who attempt withdrawal from medications. Recurrence of seizures is most likely within 6–12 months of discontinuing medications. Therefore, seizure safety precautions will need to be reinstated, including driving restriction. If seizures recur during or after withdrawal, AED therapy should be reinstated and maintained for at least another 1–2 years. The vast majority of children will again achieve remission of their seizures.

6. Blood levels of AEDs

a. General comments—Most AEDs take two or three times their half-life to reach the target serum levels indicated in Table 23–9. This must be considered when blood levels are
assessed after AEDs are started or dosages are changed. Individuals vary in their metabolism and their particular pharmacokinetic characteristics. These and external factors, including, for example, food intake or illness, also affect the blood level. Thus the level reached on a milligram per kilogram basis varies among patients. Experience and clinical research in the determination of AED blood levels have shown that there is some correlation between (1) drug dose and blood level, (2) blood level and therapeutic effect, and (3) blood level and some toxic effects.

B. Effective levels—The target serum levels listed in Table 23–9 are those within which seizure control without toxicity will be achieved in most patients. The level for any given individual will vary not only with metabolic makeup (including biochemical defects) but also with the nature and severity of the seizures and their underlying cause, and with other medications being taken, among other factors. Seizure control may be achieved at lower levels in some patients, and higher levels may be reached without toxicity in others. When control is achieved at a lower level, the dosage should not be increased merely to move the level into the therapeutic range. Likewise, toxic side effects will be experienced at different levels even within the therapeutic range. Lowering the dosage may relieve the problem, but sometimes the drug must be withdrawn or another added (or both). Some serious toxic effects, including allergic reactions and bone marrow or liver toxicity, are independent of dosage.

C. Interaction of AEDs—Blood levels of older AEDs may be affected by other drugs but this is less often the case with the newer medications. In addition to pharmacokinetic interaction, pharmacodynamic interactions may be observed, with increased side-effects despite “therapeutic” levels. Likewise, adverse effects noted with introduction of a second medication may be due to drug interactions and not to toxicity of the newly introduced medication per se.

D. Indications for determination of blood levels—There is rarely an indication for obtaining “routine” blood levels of AEDs. Thus levels should be determined for specific reasons. After a drug is introduced and seizure control is achieved, it may be useful to determine the effective level for that patient. Blood level monitoring is also useful when expected control on a usual dosage has not been achieved, when seizures recur in a patient with previously well-controlled seizures, or when there is a question of adherence to recommended treatment ("noncompliance"). A low level may indicate inadequate dosage, drug interaction, or nonadherence with the prescribed regimen. A high level may indicate slowed metabolism or excretion or drug interaction.

Blood levels are most commonly obtained when signs and symptoms of toxicity are present, especially when more than one drug is being used or when the dosage of a single drug has been changed. Blood levels may be the only means of detecting intoxication in a comatose patient, very young child, or child with severe cognitive impairment. Toxic levels also occur with drug abuse and in the presence of liver or renal disease. Blood levels are unnecessary when the patient’s seizure control is satisfactory and he or she is free of toxic signs or symptoms.

7. Side effects of AEDs—(See also Table 23–9.)

A. Idiosyncratic reactions—Serious allergic rash usually necessitates discontinuance of a drug. The risk of significant allergic rash is probably about 5–10% with carbamazepine, lamotrigine, oxcarbazepine, and phenobarbital, phenytoin. Stevens-Johnson syndrome is a risk in any child with a cutaneous eruption due to AEDs, although the degree of this risk is unclear. Not every rash in a child receiving an AED is drug-related. If a useful AED is discontinued and the rash disappears, restarting the drug in a smaller dosage may be warranted to see if the rash recurs.

Hepatic toxicity, pancreatitis, blood dyscrasias, renal stones, and other adverse systemic effects have been reported with various medications. It is not clear that routine surveillance is effective in preventing these complications of treatment. Nevertheless, routine laboratory testing is often undertaken by clinicians managing patients with epilepsy.

B. Treatment-emergent toxicity—Signs of dose-related drug toxicity such as ataxia often disappear with relatively small decreases in medication dose. The exception is phenytoin, where protein binding and so-called “zero-order kinetics” can make dose adjustments difficult.

Sedation is the most common treatment-emergent side effect of AED treatment. The sedative effect of many of these drugs may be avoided by slowly titrating medication to a moderate dose over several weeks.

Familiarity with potential side effects can allow anticipatory counseling. Gingival hyperplasia secondary to phenytoin is best minimized through good dental hygiene but occasionally requires gingivectomy. The hypertrichosis associated with phenytoin does not regress when the drug is discontinued. The risk of weight gain with valproate and gabapentin and weight loss with topiramate, zonisamide, and felbamate should be discussed on initiation of treatment. Adequate hydration and avoiding overheating on hot days can prevent the hypothermia associated with hypohidrosis in some patients treated with topiramate and zonisamide.

C. Alternative Treatments

1. Adrenocorticotropic hormone (ACTH) and corticosteroids

A. Indications—ACTH is indicated for treatment of West syndrome. The utility of other immunotherapy is less clear. Duration of ACTH therapy is guided by cessation of clinical seizures and normalization of the EEG. No specific recommendations can be made regarding dosing and duration of therapy, and multiple protocols have been advocated with initial dosing ranging from 20 U/d to 150 U/m². ACTH is often continued in full doses for 2 or more weeks and then,
if seizures have ceased, tapered over a variable length of time, usually several weeks. If seizures recur, the dosage is increased to the last effective level. Alternatively, vigabatrin may be tried. Some neurologists use longer durations of treatment, keeping the patient at the effective dosage of ACTH for up to 6 months before attempting withdrawal. There is no strong evidence, however, that longer courses of treatment are more beneficial.

Oral corticosteroids and intravenous immune globulin (IVIG) are occasionally used for pharmacoresistant epilepsy. However, dosing regimens and indications are not well established. Landau-Kleffner syndrome (acquired epileptic aphasia) is reported to respond to oral steroid treatment.

b. Dosages—For ACTH (Acthar Gel), start with 40–80 U/d or up to 150 U/m² intramuscularly in a single morning dose. Parents can be taught to give injections. For prednisone, start with 2–4 mg/kg/d orally in two or three divided doses.

c. Precautions—Give additional potassium, guard against infections, follow for possible hypertension, and discuss the cushingoid appearance and its disappearance. Do not withdraw oral corticosteroids suddenly. Side effects in some series occur in up to 40% of patients, especially with higher dosages than those listed here (used by some authorities). With long-term use, prophylaxis against Pneumocystis infection may be required. Careful and frequent follow-up is necessary. Visiting nurse services can be very helpful in surveillance such as monitoring blood pressure, weight, and potential adverse effects.

2. Ketogenic diet—A diet high in fats and low in protein and carbohydrates will result in ketosis as fatty acids replace glucose as a source of energy for cellular metabolism. Such a diet has been observed to decrease and even control seizures in some children. A ketogenic diet should be recommended in children with pharmacoresistant epilepsy, particularly those with symptomatic generalized epilepsies (astatic and myoclonic seizures and absence seizures) not responsive to drug therapy. Other seizure types may also respond. Ketosis is induced by a diet high in fats and very limited in carbohydrates with sufficient protein for body maintenance and growth. The ratio of fat-derived calories to carbohydrate and protein-derived calories is usually 4:1 in young children and somewhat lower in older children. Adding medium-chain triglycerides to the diet induces ketosis more readily than does a high level of dietary fats and thus requires less carbohydrate restriction. However, medium chain triglycerides are often not well tolerated.

Recent reports suggest efficacy with the Atkins diet or a low-glycemic index diet in older and higher functioning children who will not accept the ketogenic diet. A prepared commercially available formula is available for children receiving tube feedings. The mechanism for the anticonvulsant action of the ketogenic diet is not understood. It is, however, the ketosis, not the acidosis, that raises the seizure threshold.

The ketogenic diet requires close adherence and is often difficult for families as well as the children who cannot participate in family meals or special occasions (eg, birthday parties where cake is served). Full cooperation of all family members is required, including the patient if old enough. However, when seizure control is achieved by this method, acceptance of the diet is usually excellent. As with all therapies, potential adverse effects can occur with the ketogenic diet. These include acidosis and hypoglycemia, particularly on initiation of the diet. Thus it is prudent to admit the child for initiation of the diet after screening laboratory studies are performed to rule out underlying metabolic disorders. Renal stones can occur, and acidosis and carnitine deficiency are often seen.

3. Vagus nerve stimulator—The vagus nerve stimulator (VNS) is a recently developed treatment for medically intractable epilepsy. A pacemaker-like device is implanted below the clavicle on the left and attached to the left vagus nerve. A cycle of stimulation of the nerve is established (typically 30 seconds of stimulation every 5 minutes), which has an antiepileptic effect, reducing seizures by at least 50% in over half the children so treated. In addition, turning on the stimulator by the use of a magnet may interrupt a seizure (ie, an anticonvulsant effect). With current technology, the battery in the stimulator will last 7 or more years in many patients.

D. Surgery

An evaluation for epilepsy surgery is indicated for all children with medically intractable partial epilepsy. The evaluation and surgery should be performed at a center with expertise in epilepsy surgery and which has a dedicated neurosurgeon as well as a team of physicians and other providers.

The first surgery for treatment of epilepsy took place over 100 years ago, and surgery is now established as the appropriate treatment for adults and children with epilepsy refractory to medical treatment. Evaluation for possible surgical treatment should begin as soon as it is clear that the child is not responding to standard therapy and there is evidence of focal onset of seizures. Advances in technology allow for definition and removal of the epileptogenic focus even in young infants. Many centers now have access to video-EEG monitoring, PET, and similar noninvasive techniques that can be used to identify lesions such as cortical dysplasias that are amenable to resection. Freedom from seizures is reported in 80% or more of children who have been treated surgically. Some patients such as those with Rasmussen encephalitis or extensive perinatal strokes may be candidates for hemispherectomy. Increasingly, surgery is being performed on children with tuberous sclerosis after identification of the epileptogenic tuber.

Corpus callostomy remains an option for children who are experiencing uncontrolled drop attacks. A marked reduction in injuries due seizure-related falls is usually seen.
E. General Management of the Child with Epilepsy

1. Education—The initial diagnosis is often devastating for families. Some have been told that their child has a seizure disorder but the term epilepsy has been avoided. The patient and parents must be helped to understand the nature of epilepsy and its management, including etiology, prognosis, safety issues, and treatment options. Many children—some even as young as age 3 years—are capable of cooperating with the physician in problems of seizure control.

Excellent educational materials are available for families of a child with epilepsy, both in print and online. Two excellent web sites are http://www.epilepsyfoundation.org and http://www.epilepsy.com. Materials on epilepsy—including pamphlets, monographs, films, and videotapes suitable for children and teenagers, parents, teachers, and medical professionals—may be purchased through the Epilepsy Foundation: 8301 Professional Place, Landover, MD 20785; (800) 332-1000. The Foundation’s local chapter and other community organizations are able to provide guidance and other services. Support groups exist in many cities for older children and adolescents and for their parents and others concerned.

2. Privileges and precautions in daily life—“No seizures and no side effects” is a motto established by the Epilepsy Foundation. The child should be encouraged to live as normal a life as possible. Children should engage in physical activities appropriate to their age and social group. After seizure control is established, swimming is generally permissible with a buddy system or adequate lifeguard coverage. Scuba diving, gymnastic activities involving heights, and high climbing should not be permitted. There are no absolute contraindications to any other sports, although some physicians recommend against contact sports. Physical training and sports are usually to be welcomed rather than restricted. Driving is discussed in the next section.

Loss of sleep should be avoided. Emotional disturbances may need to be treated. Alcohol intake should be avoided because it may precipitate seizures. Prompt attention should be given to infections. Further neurologic disturbances should be brought to the physician’s attention promptly.

Although every effort should be made to control seizures, this must not interfere with a child’s ability to function. Sometimes a child is better off having an occasional mild seizure than being so heavily sedated that function at home, in school, or at play is impaired. Therapy and medication adjustment often require much art and fortitude on the physician’s part. Some patients with infrequent seizures, especially if only nocturnal partial seizures (eg, rolandic seizures) may not need AEDs.

3. Driving—Driving becomes important to most young people at age 15 or 16 years. Restrictions vary from state to state. In most states, a learner’s permit or driver’s license will be issued to an individual with epilepsy if he or she has been under a physician’s care and free of seizures for at least 1 year (although restrictions vary from state to state in the United States and in other countries), provided that the treatment or basic neurologic problems do not interfere with the ability to drive. A guide to this and other legal matters pertaining to persons with epilepsy is published by the Epilepsy Foundation, and the Foundation’s legal department may be able to provide additional information.

4. Pregnancy—Contraception (especially interaction of oral contraceptive with some AEDs) childbearing, potential teratogenicity of AEDs, and the management of pregnancy should be discussed as soon as appropriate with the adolescent young woman with epilepsy. Daily use of vitamin preparations containing folic acid is recommended. For the pregnant teenager with epilepsy, management by an obstetrician conversant with the use of AEDs in pregnancy is appropriate. The patient should be cautioned against discontinuing her medications during pregnancy. The possibility of teratogenic effects of AEDs, such as facial clefts (two to three times increased risk), must be weighed against the risks from seizures. All AEDs appear to have some risk for teratogenicity, although valproate carries a particularly high risk for spinal dysraphism.

5. School intervention and seizure response plans—Most schools will work with parents to establish a seizure action plan for their child with epilepsy. A template for such a plan is available on the Epilepsy Foundation website at http://www.epilepsyfoundation.org/programs/upload/sactionplan.pdf. These plans usually require the approval of the child’s physician. Schools are sometimes hesitant to administer Diastat or to activate the vagal nerve stimulator. Often, information from the physician, especially that obtained from the Epilepsy Foundation website, will relieve anxieties. School authorities should be encouraged to avoid needless restrictions and to address the emotional and educational needs of all children with disabilities, including epilepsy. The local affiliates of the Epilepsy Foundation can often provide support for families in their interactions with the school.

2. Status Epilepticus

Status epilepticus is a clinical or electrical seizure lasting at least 30 minutes, or a series of seizures without complete recovery over the same period of time. After 30 minutes of seizure activity, hypoxia and acidosis occur, with depletion of energy stores, cerebral edema, and structural damage. Eventually, high fever, hypotension, respiratory depression, and even death may occur. Status epilepticus is a medical emergency.

Status epilepticus is classified as (1) convulsive (the common tonic-clonic, or grand mal, status epilepticus) or (2) nonconvulsive (characterized by altered mental status or behavior with subtle or absent motor components). Absence status, or spike-wave stupor, and complex partial status epilepticus are examples of the nonconvulsive type (Table 23–10). An EEG may be necessary to aid in diagnosing nonconvulsive status
may be a cause. A study implicated viral causes in 86% of cases. Immunizations causes. Roseola infantum is a rare but classic cause. One

c. Phenobarbital, 5–20 mg/kg (sometimes higher in newborns or refractory status in intubated patients).

metabolic and endocrine disorders causes of status epilepticus in children. The cause is unknown in 50% of patients, but many of these patients will be febrile. In the child with

known epilepsy, medication nonadherence should be considered. Status epilepticus occurs most commonly in children aged 5 years and younger (85%). The most common age is 1 year or younger (37%); the distribution is even for each year thereafter (approximately 12% per year).

Clinical Findings

A child with status epilepticus may have a high fever with or without intracranial infection. Studies show that 25–75% of children with status epilepticus experience it as their initial seizure. Often it is a reflection of a acute or remote insult. Tumor and stroke, which are common causes of status epilepticus in adults, are uncommon causes in childhood. Fifty percent of pediatric status epilepticus is due to acute (25%) or chronic (25%) CNS disorders. Infection and metabolic disorders are common causes of status epilepticus in children. The cause is unknown in 50% of patients, but many of these patients will be febrile. In the child with

3. Febrile Seizures

Criteria for febrile seizures are (1) age 3 months to 5 years (most occur between ages 6 and 18 months), (2) fever of greater than 38.8°C, and (3) non-CNS infection. More than 90% of febrile seizures are generalized, last less than 5 minutes, and occur early in the illness causing the fever. Febrile seizures occur in 2–3% of children. Acute respiratory illnesses are most commonly associated with febrile seizures. Gastroenteritis, especially when caused by Shigella or Campylobacter, and urinary tract infections are less common causes. Roseola infantum is a rare but classic cause. One study implicated viral causes in 86% of cases. Immunizations may be a cause.

Rarely status epilepticus may occur during a febrile seizure. Febrile seizures rarely (1–3%) lead to recurrent unpro-
voked seizures (epilepsy) in later childhood and adult life (risk is increased two- to fivefold compared with children who do not have febrile seizures). The chance of later epilepsy is higher if the febrile seizures have complex features, such as duration longer than 15 minutes, more than one seizure in the same day, or focal features. Other adverse factors are an abnormal neurologic status preceding the seizures (eg, cerebral palsy or mental retardation), early onset of febrile seizure (before age 1 year), and a family history of epilepsy. Even with adverse factors, the risk of epilepsy after febrile seizures is still only in the range of 15–20%, although it is increased if more than one risk factor is
present. Recurrent febrile seizures occur in 30–50% of cases but in general do not worsen the long-term outlook.

Generalized epilepsy with febrile seizures plus (GEFS+) is an autosomal dominant form of epilepsy first described in 1997. The most frequently observed GEFS+ phenotype includes childhood onset of multiple febrile seizures persisting beyond the age of 6 years, and unprovoked (afebrile) seizures, including absence, myoclonic, or atonic seizures, and rarely, myoclonic-astatic epilepsy. Originally associated with a point mutation in SCN1B, GEFS+ is now known to have other channelopathies.

Clinical Findings

A. Diagnostic Evaluation

The child with a febrile seizure must be evaluated for the source of the fever, in particular to exclude CNS infection. Routine studies such as serum electrolytes, glucose, calcium, skull radiographs, or brain imaging studies are seldom helpful. A white count above 20,000/μL or an extreme left shift may correlate with bacteremia. Complete blood count and blood cultures may be appropriate. Serum sodium is often slightly low but not low enough to require treatment or to cause the seizure. Meningitis and encephalitis must be considered. Signs of meningitis (e.g., bulging fontanelle, stiff neck, stupor, and irritability) may all be absent, especially in a child younger than age 18 months.

B. Lumbar Puncture

After controlling the fever and stopping an ongoing seizure, the physician must decide whether to do a lumbar puncture. The fact that the child has had a previous febrile seizure does not rule out meningitis as the cause of the current episode. The younger the child, the more important is the procedure, because physical findings are less reliable in diagnosing meningitis. Although the yield is low, a lumbar puncture should probably be done if the child is younger than age 18 months, if recovery is slow, if no other cause for the fever is found, or if close follow-up will not be possible. Occasionally observation in the emergency department for several hours obviates the need for a lumbar puncture. A negative finding does not exclude the possibility of emergence of CNS infection during the same febrile illness. Sometimes a second procedure must be done.

Treatment & Prognosis

Prophylactic anticonvulsants are not recommended after an uncomplicated febrile seizure.

If febrile seizures are complicated or prolonged, or if medical reassurance fails to relieve family anxiety, anticonvulsant prophylaxis may be indicated and can reduce the incidence of recurrent febrile seizures. Only phenobarbital and valproic acid have demonstrated efficacy in preventing febrile seizures; phenytoin and carbamazepine have been show to be ineffective. Newer antiepileptic drugs have not been studied. Diazepam started at the first onset of fever for the duration of the febrile illness (0.5 mg/kg two or three times per day orally or rectally) may be effective but will sedate a child. Propylphylactic diazepam is also limited by the fact that a seizure is often the first evidence of fever associated with an acute illness. Diastat (rectal diazepam gel) can be used to prevent febrile status epilepticus in the child with a prolonged febrile seizure (one lasting over 5 minutes), often the greatest concern.

Phenobarbital, 3–5 mg/kg/d as a single bedtime dose, is an inexpensive long-term prophylaxis. However, significant behavioral disturbance is seen in about one third of toddlers treated with phenobarbital. Often, increasing the dosage gradually (e.g., starting with 2 mg/kg/d the first week, increasing to 3 mg/kg/d the second week, and so on) decreases side effects and nonadherence. A plasma phenobarbital level in the range of 15–40 mg/mL is desirable.

Valproate sodium is potentially more hazardous. In infants, the commonly used liquid suspension has a short half-life and causes more gastrointestinal upset than do the sprinkle capsules. The dosage is 15–60 mg/kg/d in divided doses. Precautionary laboratory studies are necessary. In the infant younger than age 2 years, there is an increased risk of hepatic toxicity. Thrombocytopenia may occur, particularly in the face of an acute illness.

Measures to control fever such as sponging or tepid baths, antipyretics, and the administration of antibiotics for proven bacterial illness are reasonable but unproven to prevent recurrent febrile seizures.

Simple febrile seizures do not have any long-term adverse consequences. An EEG may be considered if the febrile seizure is complicated, focal, or otherwise unusual. In uncomplicated febrile seizures, the EEG is usually normal. Ideally the EEG should be done at least a week after the illness to avoid transient changes due to fever or the seizure itself. In older children, 3/1 spike-wave discharges, suggestive of a genetic propensity to epilepsy, may occur. In the young infant, EEG findings seldom aid in assessing the chance of recurrence of febrile seizures or in long-term prognosis.

SYNCOPE & FAINTING

Fainting is transient loss of consciousness and postural tone due to cerebral ischemia or anoxia. Up to 20–50% of children (birth–20 years) will faint at some time. There may be a prodrome of dizziness, lightheadedness, nausea, so-called gray-out, sweating, and pallor. After falling, many children stiffen or have jerking motions when unconscious, a tonic-clonic, anoxic-ischemic seizure mimicking epilepsy. Watching or undergoing a venipuncture is a common precipitant of fainting, as is prolonged standing, fatigue, illness, over-heating and sweating, dehydration, hunger, and athleticism with slow baseline pulse. The family history is positive for similar episodes in 90% of patients.

Classification

Ninety-five percent of cases of syncope are of the vasovagal-vasodepressive or neurocardiogenic type (Table 23–12). Vasodilation, cardiac slowing, and hypotension cause transient (1–2 minutes) cerebral ischemia and result in the patient passing out. The patient arouses in 1–2 minutes, but full recovery may take an hour or more. Besides those already listed, rare precipitants include hair grooming, cough, micturition, neck stretching, and emotional stress. More ominous is cardiac syncope, which often occurs during exercise. Angina or palpitations may occur. An obstructive lesion such as aortic stenosis, cardiomyopathy, coronary disease, or dysrhythmia may be the cause. Other spells that may mimic syncope are listed in Table 23–12.

Clinical Findings

A. Symptoms and Signs

The workup of fainting includes a personal and a detailed family history, and a physical examination with emphasis on blood pressure and cardiac and neurologic features. In the adolescent, a blood pressure drop of more than 30 mm Hg after standing for 5–10 minutes or a baseline systolic pressure of less than 80 mm Hg suggests orthostasis.

B. Laboratory Findings and Imaging

Hemoglobin should be checked if anemia is suggested by the history. Electrocardiography should be done. Consider cardiology referral, Holter monitoring, and echocardiography if cardiac causes seem likely (eg, fainting during exercise). Tilt

testing (though norms are vague) may have a role in frequent recurrent syncope to confirm a vasodepressive cause and avoid more expensive diagnostic investigations.

### Treatment

Treatment consists mostly of giving advice about the benign nature of fainting and about avoiding precipitating situations. The patient should be cautioned to lie down if prodromal symptoms occur. Good hydration and reasonable salt intake are advisable. In some cases β-blockers and, rarely, fludrocortisone may have a role.

Allan WC, Gospe SM Jr: Seizures, syncope, or breath-holding presenting to the pediatric neurologist—when is the etiology a life-threatening arrhythmia? Semin Pediatr Neurol 2005;12:2 [PMID: 15929459].

### HEADACHES

Headache is one of the most common complaints in pediatric neurology clinics, accounting for 25–30% of all referrals. Epidemiologic studies indicate that headache occurs in 37% of children by age 7 years and in 69% of children by age 14 years. Migraine headache occurs in 5% and 15%, respectively, of children at these ages. Successful treatment requires an accurate diagnosis and proper classification of headache. Based on the patient’s history, a simplified initial categorization as summarized in Table 23–13 can be made. A more exhaustive classification scheme has been developed by the International Headache Society and modified for use in children. Muscle contraction tension headaches are common in older children and adolescents. They are frequently generalized over the head with a “hat band” pressure or squeezing quality. Although appetite may be diminished, nausea and vomiting are usually not present. Symptoms specifically referable to the CNS are absent. If this type of headache becomes very frequent (three or more days per week) consideration should be given to drug (analgesic) overuse or misuse, depression, or sleep disorder. The neurologic examination is normal, neuroimaging tests are generally not needed, and treatment is judicious use of ibuprofen with or without a prophylactic (daily, at bedtime) trial of amitriptyline. If simple measures are not satisfactory, biofeedback, hypnosis, other relaxation methods, psychotherapy, or a combination of these methods may be useful.

Between 65% and 75% of children referred to neurology clinics for consultation regarding headaches have migraine. Many of these children are referred after they have seen ophthalmologists for “eye strain” or otolaryngologists to rule out sinusitis. Approximately 30% of children are referred after already undergoing one or more neuroimaging tests, the vast majority of which show normal results.

#### Clinical Findings

The diagnosis and proper classification of migraine depends primarily on a thorough and detailed history (Table 23–14). Migraine headaches are paroxysmal, recurrent events separated by symptom-free intervals in a child with normal growth.

and development and whose neurologic examination is normal. Migraine affects children of all ages but is difficult to diagnose before age 4 years. The family history is positive for vascular, migrainous headaches in 75% of patients. The headaches have a pulsatile quality and are located unilaterally or bilaterally in the frontal or temporal regions, or commonly in the retro-orbital and cheek regions. The headaches last from 2 to more than 24 hours. A nonspecific prodrome of decreased or increased appetite and change in mood and temperament may precede the headache by hours or days. Headaches may be triggered by specific foods, minor head injuries, sleep deprivation, or irregular eating patterns, but more often no precipitant can be identified. An aura such as visual scotomata is uncommon in children. The headache is frequently accompanied by nausea, vomiting, photophobia, sensitivity to sound, vertigo, lightheadedness, fatigue, and mood alterations. Occasionally children may have loss of speech, hemiparesis, ataxia, confusional states, and bizarre visual distortions (so-called Alice in Wonderland syndrome). Very young children may experience recurrent or cyclical vomiting, abdominal pain, or recurrent self-limited bouts of ataxia or vertigo as the early manifestations of migraine.

Occasionally the frequency of migraine may spontaneously increase and become an almost daily occurrence, a condition referred to as transformed migraine. When papilledema is present but the MRI is normal, a lumbar puncture may be needed to diagnose pseudotumor cerebri.

### Treatment

Successful treatment of migraine is usually achieved with the systematic use of simple analgesics such as ibuprofen. The key to successful results is to take enough early enough to do the job. As soon as possible after the headache starts, the child is given ibuprofen, 10 mg/kg, followed in 45 minutes by 5 mg/kg if needed. Additional doses of analgesics rarely provide additional benefit. The addition of 40–65 mg of caffeine, caffeine-ergotamine combinations, or 65 mg of isometheptene (Midrin) to ibuprofen may provide more reliable relief for some patients. Nausea and vomiting can be treated with metoclopramide, taken 10–20 minutes before other medications. For frequently recurring migraine, prophylaxis (twice daily or single dose at bedtime) with propranolol, amitriptyline, cyproheptadine, valproate, or topiramate should be considered; however, none of these agents has had carefully double-blinded, controlled trials in children or teens. At this time experience with using triptan and dihydroergotamine (nasal spray) in young children is limited; in teens, studies show sumatriptan and zolmitriptan nasal sprays to be effective (although after-taste can be sometimes daunting). Oral triptans and dihydroergotamine have been shown to be effective compared with placebo and are safe and inexpensive; most studies have been done in adolescents. Biofeedback, relaxation therapy, and other nonpharmacologic approaches to managing headache may be useful in children, and they provide an alternative method of treatment that avoids medication-related side effects.

\(^a\)Idiopathic recurring disorder; headache usually lasts 1–48 h.

IHS, International Headache Society.

60% are between puberty and their late teens. Narcolepsy, a primary disorder of sleep, is characterized by chronic, excessive daytime sleeping that occurs regardless of activity or surroundings and is not relieved by increased sleep at night. Onset occurs as early as age 3 years. Of children with narcolepsy, 18% are younger than age 10, and 60% are between puberty and their late teens. Narcolepsy usually interferes severely with normal living. Months to years after onset, there may also be cataplexy (transient partial or total loss of muscle tone, often triggered by laughter, anger, or other emotional upsurge), hypnagogic hallucinations (visual or auditory), and sensations of paralysis on falling asleep. Studies have shown that rapid eye movement (REM) sleep, with loss of muscle tone and an EEG low-amplitude mixed frequency pattern, occurs soon after sleep onset in patients with cataplexy, whereas normal subjects experience 80–100 minutes or longer of non-REM (NREM) sleep before the initial REM period.

Recent research suggests absence of a hypothalamic neuropeptide, hypocretin, causes narcolepsy and cataplexy. Spinal fluid (but not plasma) levels of hypocretin-1 (also called orexin) are diagnostic (level will be zero). The condition persists throughout life.

Modafinil is a new effective treatment for narcolepsy or excessive daytime sleepiness. Other CNS stimulants may have a role. Amphetamine mixtures (Adderall) or long-acting methylphenidate are examples. Cataplexy responds to venlafaxine, fluoxetine, or clomipramine. Rarely, acute narcolepsy/cataplexy (autoimmune) responds to IVIG.

3. Somnambulism (Sleepwalking)
(See also Chapter 2)

Somnambulism and somniloquy (sleep talking) are among a group of sleep disturbances known as disorders of arousal. The onset is abrupt, usually early in the night. It is characterized by coordinated activity (eg, walking and sometimes moving objects seemingly without purpose) in a state of veiled consciousness. The episode is relatively brief and ceases spontaneously. There is poor recall of the event on waking in the morning. Somnambulism may be related to mental activities occurring in stages 3 and 4 of NREM sleep. Incidence has been estimated at only 2–3%, but up to 15% of cases are reported in children aged 6–16 years. Boys are affected more often than girls, and many have recurrent episodes. Psychopathologic features are rarely demonstrated, but a strong association (30%) between childhood migraine and somnambulism has been noted. Episodes of somnambulism may be triggered in predisposed children by stresses, including febrile illnesses. No treatment of somnambulism is required, and it is not necessary to seek psychiatric consultation.

4. Night Terrors (See also Chapter 2)

Night terrors (pavor nocturnus) are a disorder of arousal from NREM sleep. Most cases occur in children aged 3–8 years, and the disorder rarely occurs after adolescence. It is characterized by sudden (but only partial) waking, with the severely frightened child unable to be fully roused or comforted. Concomitant autonomic symptoms include rapid breathing, tachycardia, and perspiring. The child has no recall of any nightmare. Psychopathologic mechanisms are unclear, but falling asleep after watching scenes of violence
on television or hearing frightening stories may play a role. Elimination of such causes and consideration of a sleep study (polysomnogram) to rule out obstructive apnea and partial complex seizures may have a role. Most of the time, watchful waiting and reassurance of the family are sufficient.

5. Restless Legs Syndrome (See also Chapter 2)

Restless legs syndrome refers to continuous, bothersome leg movements occurring at rest and producing unpleasant paresthesias (sensory symptoms) that often interfere with restful sleep. Occasionally, anemia (low ferritin) has been noted in adults with the disorder; in these cases improvement has occurred with ferrous sulfate treatment. Avoidance of caffeine, nicotine, alcohol, and some drugs (antidepressants, neuroleptics) has helped in adult series. No pediatric medication studies exist; anecdotally, clonazepam, possibly clonidine, and gabapentin are safe options. Dopa agonists, ropinirole, and pramipexole, used in adults, are unproven in children but also likely safe. (See also Chapter 2.)

**PSEUDOTUMOR CEREBRI**

Pseudotumor cerebri is characterized by increased intracranial pressure in the absence of an identifiable intracranial mass or hydrocephalus. An obese teenage girl (or adult) is the typical phenotype. Symptoms are headache, tinnitus, and visual loss; signs are those of increased intracranial pressure as outlined in Table 23–15. The cause is usually unknown, but pseudotumor cerebri has been described in association with a variety of inflammatory, metabolic, toxic, and connective tissue disorders (Table 23–16). The diagnosis of pseudotumor cerebri is one of exclusion. MRI scan of the head is needed to exclude hydrocephalus and intracranial masses. This study demonstrates ventricles of small or normal size but no other structural abnormalities. Venous thrombosis, an underrecognized cause, must be ruled out by magnetic resonance venogram or even injected venograms of cerebral sinuses. Lumbar puncture should be performed to document elevated CSF pressure. Examination of CSF reveals normal findings except for elevated pressure. In some inflammatory and connective tissue diseases, however, the CSF protein concentration may be increased.

Treatment of pseudotumor cerebri is aimed at correcting the identifiable predisposing condition. In addition, some

patients may benefit from the use of furosemide or acetazolamide to decrease the volume and pressure of CSF within the CNS. These drugs may be used in combination with repeated lumbar punctures to remove CSF. If a program of repeated CSF removal and medical management is not successful or if central vision or visual field loss is detected despite these measures, lumboperitoneal or ventriculoperitoneal shunt or optic nerve fenestration may be necessary to prevent irreparable visual loss and damage to the optic nerves.

CEREBROVASCULAR DISEASE

Pediatric arterial ischemic stroke is subdivided into two categories: neonatal arterial ischemic stroke (neonatal stroke) and childhood arterial ischemic stroke (childhood stroke). Generally, neonatal stroke is defined as arterial ischemia occurring in a patient younger than age 28 days and older than 28 weeks’ gestation. Childhood stroke is any stroke occurring in a patient between 28 days and 18 years old.

1. Childhood Stroke

Childhood stroke is emerging as a serious and increasingly recognized disorder, affecting 2–8:100,000 children. There are numerous adverse outcomes, which include death in 10%, neurologic deficits or seizures in 50–85%, and recurrent strokes in 20–35%. The initial approach to the patient should recognize that childhood stroke represents a neurologic emergency, for which promptness in diagnosis can affect treatment considerations and outcome. Unfortunately, most pediatric stroke is not recognized until 24–36 hours after onset; treatment considerations matter most in the first hours after stroke onset. When possible, all children who present with stroke should be transferred to a tertiary care center that specializes in pediatric stroke management. The evaluation should include a thorough history of prior illnesses, especially those associated with varicella (even in the prior 1–2 years) influenza, parvovirus B19, HIV, minor trauma to the head and neck, and familial clotting tendencies. A systematic search for evidence of cardiac, vascular, hematologic, or intracranial disorders should be undertaken (Table 23–17). Although many strokes are not associated with a single underlying systemic disorder, previously diag-

nosed congenital heart disease is the most common predisposing illness, followed by hematologic and neoplastic disorders. In many instances the origin is multifactorial, necessitating a thorough investigation even when the cause may seem obvious. As a result, the cause of childhood stroke is increasingly determined, whereas in past studies up to 30% remained idiopathic. This is particularly important when considering that recurrence risk may be as high as 35%.

Clinical Findings

A. Symptoms and Signs

Manifestations of stroke in childhood vary according to the vascular distribution to the brain structure that is involved. Because many conditions leading to childhood stroke result in emboli, multifocal neurologic involvement is common. Children may present with acute hemiplegia similarly to stroke in adults. Symptoms of unilateral weakness, sensory disturbance, dysarthria, and dysphagia may develop over a period of minutes, but at times progressive worsening of symptoms may evolve over several hours. Bilateral hemispheric involvement may lead to a depressed level of consciousness. The patient may also demonstrate disturbances of mood and behavior and experience focal or multifocal seizures. Physical examination of the patient is aimed not only at identifying the specific deficits related to impaired cerebral blood flow, but also at seeking evidence for any predisposing disorder. Retinal hemorrhages, splinter hemorrhages in the nail beds, cardiac murmurs, rash, neurocutaneous stigmata, and signs of trauma are especially important findings.

B. Laboratory Findings and Ancillary Testing

In the acute phase, certain investigations should be carried out emergently with consideration of treatment options. This should include complete blood count, erythrocyte sedimentation rate, basic chemistries, blood urea nitrogen, creatinine, prothrombin time/partial thromboplastin time, chest radiography, electrocardiography, urine toxicology, and imaging (see following section). Subsequent studies can be carried out systemically, with particular attention paid to disorders involving the heart, blood vessels, platelets, red cells, hemoglobin, and coagulation proteins. Twenty to 50% of all pediatric stroke patients will have a prothrombotic state. Additional laboratory tests for systemic disorders such as vasculitis, mitochondrial disorders, and metabolic disorders are sometimes indicated.

Examination of CSF is indicated in patients with fever, nuchal rigidity, or obtundation when the diagnosis of intracranial infection requires exclusion. Lumbar puncture may be deferred until a neuroimaging scan (excluding brain abscess or a space-occupying lesion that might contraindicate lumbar puncture) has been obtained. In the absence of infection and frank intracranial subarachnoid hemorrhage, CSF examination is rarely helpful in defining the cause of the cerebrovascular disorder.

When seizures are prominent, an EEG may be used as an adjunct in the patient’s evaluation. An EEG and sequential EEG monitoring may help in patients with severely depressed consciousness.

Electrocardiography and echocardiography are useful both in the diagnostic approach to the patient and in ongoing monitoring and management, particularly when hypotension or cardiac arrhythmias complicate the clinical course.

C. Imaging

CT and MRI scans of the brain are helpful in defining the extent of cerebral involvement with ischemia or hemorrhage. CT scans may be normal within the first 12–24 hours of an ischemic stroke and may need to be repeated. CT scan early after the onset of neurologic deficits is valuable in excluding intracranial hemorrhage. This information may be helpful in the early stages of management and in the decision to treat with anticoagulants. State-of-the-art management of stroke in the adult population omits CT scanning but proceeds directly to urgent MRI, MRA, and diffusion-weighted imaging since these modalities are sensitive to acute stroke in the initial 3 hours, when intravenous thrombolytics might be considered. Increasingly, MRI with diffusion-weighted imaging is becoming the standard of care in diagnosing pediatric stroke.

Vascular imaging is an important part of pediatric stroke management and may include CTA, MRA, or conventional angiography. In studies in which both MRA and cerebral angiography have been used, up to 80% of patients with ischemic stroke have demonstrated a vascular abnormality. Vascular imaging is helpful in diagnosing disorders such as transient cerebral arteriopathy, arteriopathy associated with sickle cell disease, moyamoya disease, arterial dissection, aneurysm, fibromuscular dysplasia, and chronic inflammatory vasculitis. Recent studies have demonstrated that patients with vascular abnormalities on MRA or conventional angiography have a much greater recurrence risk than patients with normal vessels. When vessel imaging is performed, all major vessels should be studied from the aortic arch. If evidence of fibromuscular dysplasia is present in the intracranial or extracranial vessels, renal arteriography is indicated.

Differential Diagnosis

Patients with an acute onset of neurologic deficits must be evaluated for other disorders that can cause focal neurologic deficits. Hypoglycemia, prolonged focal seizures, a prolonged postictal paresis (Todd paralysis), acute disseminated encephalomyelitis, meningitis, encephalitis, and brain abscess should all be considered. Migraine with focal neurologic deficits may be difficult to differentiate initially from ischemic stroke. Occasionally the onset of a neurodegenerative disorder (eg, adrenoleukodystrophy or mitochondrial disorder) may begin with the abrupt onset of seizures and focal neurologic deficits. The possibility of drug abuse (particularly
sections of the brain. When a stroke occurs in an immature brain, the outcome can vary widely. The infant or child may experience varying degrees of neurologic deficit depending on the size and location of the affected area and the extent of brain plasticity. Approximately 20–40% of patients who experience neonatal strokes are neurologically normal. Motor impairment affects about 20–30% of all patients who experience neonatal strokes, and 30% are severely affected. Underlying predisposing conditions and the vascular territory involved all play a role in dictating the outcome for an individual patient. When the stroke involves extremely large sections of one hemisphere or large portions of both hemispheres and cerebral edema develops, the patient’s level of consciousness may deteriorate rapidly, and death may occur within the first few days. Some patients may achieve almost complete recovery of neurologic function within several days if the cerebral territory is small. Seizures, either focal or generalized, may occur in 30–50% of patients at some point in the course of their cerebrovascular disorder. Recurrence is 20–35%, and is more prominent in some conditions, such as protein C deficiency, lipoprotein (a) abnormalities and arteriopathies. Chronic problems with learning, behavior, and activity are common. Long-term follow-up with a multidisciplinary stroke team is indicated.

2. Neonatal Stroke

Neonatal stroke is more common than childhood stroke, affecting 1:4000 children. Neonatal stroke has two distinct presentations: acute and delayed. Most patients with an acute presentation develop neonatal seizures during the first week of life, usually in association with a perinatal event. The seizures in acute neonatal stroke are often focal motor seizures of the contralateral arm and leg. The presentation is stereotypical because of the predilection of the stroke to occur in the middle cerebral artery. The presence of diffusion-weighted abnormalities on an MRI scan confirms an acute perinatal stroke during the first week of life. Others present with delayed symptoms, typically with an evolving hemiparesis at an average of 4–8 months.

Acute treatment of a neonatal stroke is usually limited to neonates with seizures. Unless an embolic source is identified, aspirin and anticoagulation are usually deferred. Management is based on supportive care, identification of comorbid conditions, and treatment of seizures. In acute neonatal stroke, treatable causes of the stroke such as infection, cardiac embolus, metabolic derangement, and dissection must be ruled out. In appropriate cases, echocardiography, MRA, and lumbar puncture are indicated. Supportive management focuses on general measures, such as normalizing glucose levels, monitoring blood pressure, and optimizing oxygenation.

Long-term management of neonatal stroke usually starts with identifying risk factors, which might include prothrombotic states, cardiac disease, drugs, and dehydration. Although prothrombotic abnormalities with the best evidence of association are factor V Leiden, protein C deficiency, and lipoprotein (a), many neurologists perform an extensive hemostatic workup. Maternal risk factors such as infertility, antiphospholipid antibodies, placental infection, premature rupture of membranes, and cocaine exposure are all independently associated with neonatal stroke. The prognosis for children who sustain neonatal strokes is generally better than for children or adults with strokes, presumably because of the plasticity of the neonatal brain. Twenty to 40% of patients who experience neonatal strokes are neurologically normal. Motor impairment affects about
40% of patient and is predominantly hemiplegic cerebral palsy. In acute presentations, MRI can be predictive of motor impairment, as descending corticospinal tract diffusion-weighted MRI signal is associated with a higher incidence of hemiplegia. Language delays, behavioral abnormalities, and cognitive deficits are seen in 20–30% of infants who experience neonatal strokes. Patients are also at an increased risk for seizures. Stroke recurs in 3% of neonates and is usually associated with a prothrombotic abnormality or an underlying illness, such as cardiac malformation or infection. Given the low incidence of recurrence, long-term management is largely rehabilitative, including constraint therapies.

CONGENITAL MALFORMATIONS OF THE NERVOUS SYSTEM

Malformations of the nervous system occur in 1–3% of living neonates and are present in 40% of infants who die. Developmental anomalies of the CNS may result from a variety of causes, including infectious, toxic, metabolic, and vascular insults that affect the fetus. The specific type of malformation that results from such insults, however, may depend more on the gestational period during which the insult occurs than on the specific cause. The period of induction, days 0–28 of gestation, is the period during which the neural plate appears and the neural tube forms and closes. Insults during this phase can result in a major absence of neural structures, such as anencephaly, or in a defect of neural tube closure, such as spina bifida, meningo(myelo)cele, or encephalocele. Cellular proliferation and migration characterize neural development that occurs after 28 days’ gestation. Lissencephaly, pachygyria, agyria, and agenesis of the corpus callosum may be the result of disruptions (genetic, toxic, infectious, or metabolic) that can occur during the period of cellular proliferation and migration.

1. Abnormalities of Neural Tube Closure

Defects of neural tube closure constitute some of the most common congenital malformations affecting the nervous system, occurring in 1:1000 live births. Spina bifida with associated meningo(myelo)cele or meningocele is commonly found in the lumbar region. Depending on the extent and severity of the involvement of the spinal cord and peripheral nerves, lower extremity weakness, bowel and bladder dysfunction, and hip dislocation may be present. Delivery via cesarean section followed by early surgical closure of meningoceles and meningo(myelo)celes is usually indicated. Additional treatment is necessary to manage chronic abnormalities of the urinary tract, orthopedic abnormalities such as kyphosis and scoliosis, and paresis of the lower extremities. Hydrocephalus associated with meningo(myelo)cele usually requires ventriculoperitoneal shunting.

A. Arnold-Chiari Malformations

Arnold-Chiari malformation type I consists of elongation and displacement of the caudal end of the brainstem into the spinal canal with protrusion of the cerebellar tonsils through
the foramen magnum. In association with this hindbrain malformation, minor to moderate abnormalities of the base of the skull often occur, including basilar impression (platybasia) and small foramen magnum. Arnold-Chiari malformation type I may remain asymptomatic for years, but in older children and young adults it may cause progressive ataxia, paresis of the lower cranial nerves, and progressive vertigo; rarely it may present with apnea or disordered breathing. Posterior cervical laminectomy may be necessary to provide relief from cervical cord compression. Venticuloperitoneal shunting is required for hydrocephalus.

Arnold-Chiari malformation type II consists of the malformations found in Arnold-Chiari type I plus an associated lumbar meningomyelocele. Hydrocephalus develops in approximately 90% of children with Arnold-Chiari malformation type II. These patients may also have aqueductal stenosis, hydromyelia or syringomyelia, and cortical dysplasias. The clinical manifestations of Arnold-Chiari malformation type II are most commonly caused by the associated hydrocephalus and meningomyelocele. In addition, dysfunction of the lower cranial nerves may be present. Up to 25% of patients may have epilepsy, likely secondary to the cortical dysplasias. Higher lesions of the thoracic or upper lumbar cord are associated with mild mental retardation in about half of patients, while over 85% of patients with lower level lesions have normal intelligence quotients (IQs). Many patients will develop a latex sensitivity or allergy.

Arnold-Chiari malformation type III is characterized by occipital encephalocele, a closure defect of the rostral end of the neural tube. Hydrocephalus is extremely common with this malformation.

B. Diagnosis and Prevention

In general, the diagnosis of neural tube defects is obvious at the time of birth. The diagnosis may be strongly suspected prenatally on the basis of ultrasonographic findings and the presence of elevated α-fetoprotein in the amniotic fluid. All women of childbearing age should take prophylactic folate, which can prevent these defects and decrease the risk of recurrence by 70%.

2. Disorders of Cortical Development

Malformations of cortical development are increasingly recognized with the advent of MRI techniques and the explosion of newly identified genetic syndromes. They are subdivided into disorders based on their etiology: neuronal migration, cortical organization, abnormal proliferation or apoptosis, and unclassified. In this section we provide some common examples of these subtypes. Lissencephaly is the most common disorder of neuronal migration. Polymicrogyria and schizencephaly are examples of organizational abnormalities. Agenesis of the corpus callosum, described below, is an example of abnormal apoptosis. Finally, some abnormalities such as Dandy-Walker syndrome remained unclassified.

A. Lissencephaly

Lissencephaly is a severe malformation of the brain characterized by an extremely smooth cortical surface with minimal sulcal and gyral development. Such a smooth surface is characteristic of fetal brain at the end of the first trimester. In addition, lissencephalic brains have a primitive cytoarchitectural construction with a four-layered cerebral mantle instead of the mature six-layered mantle. Pachygyria (thick gyri) and agyria (absence of gyri) may vary in an anterior to posterior gradient, which can be suggestive of the underlying genetic defect. Patients with lissencephaly usually have severe neurodevelopmental delay, microcephaly, and seizures (including infantile spasms); however, there is significant phenotypic heterogeneity, which can depend on the specific mutation. These disorders are autosomal recessive, except for the X-linked disorders. LIS1 mutations on chromosome 17 are associated with dysmorphic features (Miller-Dieker syndrome). Another autosomal recessive mutation, involving the RELN gene, results in a lissencephaly with severe hippocampal and cerebellar hypoplasia. X-linked syndromes involving mutations in DCX (double cortin) and ARX (associated with ambiguous genitalia) affect males with lissencephaly and females with band heterotopias or agenesis of the corpus callosum. Lissencephaly in association with hydrocephalus, cerebellar malformations, and muscular dystrophy may occur in Walker-Warburg syndrome (POMT1 mutation), Fukuyama muscular dystrophy (fukutin mutation), and muscle-eye-brain disease (POMGnTI mutation). It is particularly important to identify these syndromes not only because clinical tests are available, but also because of their genetic implications. Lissencephaly may also be a component of Zellweger syndrome, a metabolic peroxisomal abnormality associated with the presence of elevated concentrations of very-long-chain fatty acids in plasma. No specific treatment for lissencephaly is available, and seizures are often difficult to control with standard medications.

MRI scans have helped to define several presumed migrational defects that are similar to but anatomically more restricted than lissencephaly. A distinctive example is bilateral perisylvian cortical dysplasia. Patients with this disorder have pseudobulbar palsy, variable cognitive deficits, facial diplegia, dystarthis, developmental delay, and epilepsy. Seizures are often difficult to control with antiepileptic drugs; some patients have benefited from corpus callosotomy. The cause of this syndrome is as yet unknown, although intraventricular cerebral ischemic injury has been postulated. Therapy is aimed at improving speech and oromotor functions and controlling seizures.

B. Agenesis of the Corpus Callosum

Agenesis of the corpus callosum, once thought to be a rare cerebral malformation, is more frequently diagnosed with modern neuroimaging techniques; occurring in 1:4000 births. The cause of this malformation is unknown. Occa-
Craniosynostosis, or premature closure of cranial sutures, is usually sporadic and idiopathic. However, some patients have hereditary disorders, such as Apert syndrome and Crouzon disease, that are associated with abnormalities of the digits, extremities, and heart. Occasionally craniosynostosis may be associated with an underlying metabolic disturbance such as hyperthyroidism and hypophosphatasia. The most common form of craniosynostosis involves the sagittal suture and results in scaphocephaly, an elongation of the head in the anterior to posterior direction. Premature closure of the coronal sutures causes brachycephaly, an increase in cranial growth from left to right. Unless many or all cranial sutures close prematurely, intracranial volume will not be compromised, and the brain’s growth will not be impaired. Closure of only one or a few sutures will not cause impaired brain growth or neurologic dysfunction. Management of craniosynostosis is directed at preserving normal skull shape and consists of excising the fused suture and applying material to the edge of the craniectomy to prevent reossification of the bone edges. The best cosmetic effect on the skull is achieved when surgery is performed during the first 6 months of life.

4. Hydrocephalus

Hydrocephalus is characterized by an increased volume of CSF in association with progressive ventricular dilation. In communicating hydrocephalus, CSF circulates through the ventricular system and into the subarachnoid space without obstruction. In noncommunicating hydrocephalus, an obstruction blocks the flow of CSF within the ventricular system or blocks the egress of CSF from the ventricular system into the subarachnoid space. A wide variety of disorders, such as hemorrhage, infection, tumors, and congenital malformations, may play a causal role in the development of hydrocephalus. Attention to an X-linked inheritance pattern, the presence of radialized thumbs and aqueductal stenosis, is suggestive of X-linked hydrocephalus due to the clinically testable neural cell adhesion molecule-L1 deficiency.

Clinical features of hydrocephalus include macrocephaly, an excessive rate of head growth, irritability, vomiting, loss of appetite, impaired upgaze, impaired extraocular movements, hypertonia of the lower extremities, and generalized hyperreflexia. Without treatment, optic atrophy may occur. In infants, papilledema may not be present, whereas older children with closed cranial sutures can eventually develop swelling of the optic disk. Hydrocephalus can be diagnosed on the basis of the clinical course, findings on physical examination, and CT or MRI scan.

Treatment of hydrocephalus is directed at providing an alternative outlet for CSF from the intracranial compartment. The most common method is ventriculoperitoneal shunting. Other treatment should be directed, if possible, at the underlying cause of the hydrocephalus.

For genetic testing, see http://www.genetests.org
ABNORMAL HEAD SIZE

Bone plates of the skull have almost no intrinsic capacity to enlarge or grow. Unlike long bones, they depend on extrinsic forces to stimulate new bone formation at the suture lines. Although gravity and traction on bone by muscle and scalp probably stimulate some growth, the single most important stimulus for head growth during infancy and childhood is brain growth. Therefore, accurate assessment of head growth is one of the most important aspects of the neurologic examination of young children. A head circumference that is two standard deviations above or below the mean for age requires investigation and explanation.

1. Plagiocephaly

An abnormal skull shape is plagiocephaly (“oblique head”). Flatness of the head (brachycephaly) is a common complaint, and nowadays is usually secondary to supine sleep position (“back to sleep”), not from occipital lambdoid suture craniosynostosis.

Repositioning the head during naps (eg, with a rolled towel under one shoulder), and “tummy time” when awake are remedies. Rarely is a skull film or consultation necessary to rule out craniosynostosis. Most positional nonsynostotic plagiocephaly resolves by age 2 years.

2. Microcephaly

A head circumference more than two standard deviations below the mean for age and sex is by definition microcephaly. More important, however, than a single head circumference measurement is the rate or pattern of head growth over time. Head circumference measurements that progressively drop to lower percentiles with increasing age are indicative of a process or condition that has impaired the brain’s capacity to grow. The causes of microcephaly are numerous. Some examples are listed in Table 23–18.

Clinical Findings

A. Symptoms and Signs

Microcephaly may be suspected in the full-term newborn and in infants up to age 6 months whose chest circumference exceeds the head circumference (unless the child is very obese). Microcephaly may be discovered when the child is examined because of delayed developmental milestones or neurologic problems, such as seizures or spasticity. There may be a marked backward slope of the forehead (as in familial microcephaly) with narrowing of the bitemporal diameter. The fontanelle may close earlier than expected, and sutures may be prominent.

B. Laboratory Findings

Laboratory findings vary with the cause. Abnormal dermatoglyphics may be present when the injury occurred before 19 weeks’ gestation. In the newborn, IgM antibody titers for toxoplasmosis, rubella, cytomegalovirus (CMV), herpes simplex virus, and syphilis may be assessed. Elevated specific IgM titer is indicative of congenital infection. The urine culture for CMV will be positive at birth when this virus is the cause of microcephaly. Eye, cardiac, and bone abnormalities may also be clues to congenital infection. The child’s serum and urine amino and organic acid determinations are occasionally diagnostic. The mother may require screening for phenylketonuria. Karyotyping should be considered.

C. Imaging

CT or MRI scans may aid in diagnosis and prognosis. These studies may demonstrate calcifications, malformations, or atrophic patterns that suggest specific congenital infections or genetic syndromes. Plain skull radiographs are of limited

value. Genetic counseling should be offered to the family of any infant with significant microcephaly.

### Differential Diagnosis

Congenital craniosynostosis involving multiple sutures is easily differentiated by inspection of the head, history, identification of syndromes, hereditary pattern, and sometimes signs and symptoms of increased intracranial pressure. Common forms of craniosynostosis involving sagittal, coronal, and lambdoidal sutures are associated with abnormally shaped heads but do not cause microcephaly. Recognizing treatable causes of undergrowth of the brain such as hypopituitarism or hypothyroidism and severe protein-calorie undernutrition is critical so that therapy can be initiated as early as possible.

### Treatment & Prognosis

Except for the treatable disorders already noted, treatment is usually supportive and directed at the multiple neurologic and sensory deficits, endocrine disturbances (eg, diabetes insipidus), and seizures. Many, but not all, children with microcephaly are developmentally delayed. The notable exceptions are found in cases of hypopituitarism (rare) or familial autosomal dominant microcephaly.

3. Macrocephaly

A head circumference more than two standard deviations above the mean for age and sex denotes macrocephaly. Rapid head growth rate suggests increased intracranial pressure, most likely caused by hydrocephalus, extra-axial fluid collections, or neoplasms. Macrocephaly with normal head growth rate suggests familial macrocephaly or true megalencephaly, as might occur in neurofibromatosis. Other causes and examples of macrocephaly are listed in Table 23–19.

### Clinical Findings

Clinical and laboratory findings vary with the underlying process. In infants, transillumination of the skull with an intensely bright light in a completely darkened room may disclose subdural effusions, hydrocephalus, hydranencephaly, and cystic defects. A surgically or medically treatable condition must be ruled out. Thus the first decision is whether and when to perform an imaging study.

#### A. Imaging Study Deferred

1. **Catch-up growth**—Catch-up growth may be evident, as it is in the thriving, neurologically intact premature infant whose rapid head enlargement is most marked in the first weeks of life, or the infant in the early phase of recovery from deprivation dwarfism. As the expected normal size is reached, head growth slows and then resumes a normal growth pattern. If the fontanelle is open, cranial ultrasonography can assess ventricular size and diagnose or exclude hydrocephalus.

2. **Familial macrocephaly**—This condition may exist when another family member has an unusually large head with no

---

signs or symptoms referable to such disorders as neurocutaneous dysplasias (especially neurofibromatosis) or cerebral gigantism (Sotos syndrome), or when there are no significant mental or neurologic abnormalities in the child.

B. Imaging Study

CT or MRI scans (or ultrasonography, if the anterior fontanelle is open) are used to define any structural cause of macrocephaly and to identify an operable disorder. Even when the condition is untreatable (or does not require treatment), the information gained may permit more accurate diagnosis and prognosis, guide management and genetic counseling, and serve as a basis for comparison should future abnormal cranial growth or neurologic changes necessitate a repeat study. An imaging study is necessary if signs or symptoms of increased intracranial pressure are present (see Table 23–15).

NEUROCUTANEOUS DYSPLASIAS

Neurocutaneous dysplasias are diseases of the neuroectoderm and sometimes involve endoderm and mesoderm. Birthmarks—and skin growths appearing later—often suggest a need to look for brain, spinal cord, and eye disease. Hamartomas (histologically normal tissue growing abnormally rapidly or in aberrant sites) are common. The most common dysplasias are dominantly inherited. Benign and even malignant tumors may develop.

1. Neurofibromatosis (von Recklinghausen Disease)

<table>
<thead>

<th>ESSENTIALS OF DIAGNOSIS &amp; TYPICAL FEATURES</th>
</tr>
</thead>
<tbody>
<tr>
<td>More than six café-au-lait spots 5 mm in greatest diameter in prepubertal individuals and over 15 mm in greatest diameter in postpubertal individuals.</td>
</tr>
</tbody>
</table>

- Two or more neurofibromas of any type or one plexiform neurofibroma.
- Freckling in the axillary or inguinal regions.
- Optic glioma.
- Two or more Lisch nodules (iris hamartomas).
- Distinctive bony lesions, such as sphenoid dysplasia or thinning of long bone with or without pseudarthroses.
- First-degree relative (parent, sibling, offspring) with neurofibromatosis type 1 by above criteria.

General Considerations

Neurofibromatosis is a multisystem disorder with a prevalence of 1:3000–4000. Fifty percent of cases are due to new mutations in the NF1 gene. Forty percent of patients will develop medical complications of the disorder in their lifetime.

Clinical Findings

A. Symptoms and Signs

The most common presenting symptoms are cognitive or psychomotor problems; 40% of patients have learning disabilities, and mental retardation occurs in 8%. The family history is important in identifying dominant gene manifestations in parents. Parents should be examined in detail. The history should focus on lumps or masses causing disfigurement, functional problems, or pain. Café-au-lait spots are seen in most affected children by age 1 year. The typical skin lesion is 10–30 mm, ovoid, and smooth-bordered. Discrete tumors are more common, are well demarcated, and can occur at any age. Plexiform neurofibromas are more diffuse and can invade normal tissue. They are congenital and are frequently detected during periods of rapid growth. If the face or a limb is involved, there may be associated hypertrophy or overgrowth.

The clinician should ask about visual problems. Strabismus or amblyopia dictates a search for optic glioma, a common tumor in neurofibromatosis. Any progressive neurologic deficit calls for studies to rule out tumor of the spinal cord or CNS. Tumors of cranial nerve VIII virtually never occur in neurofibromatosis type 1 but are the rule in neurofibromatosis type 2, a rare autosomal dominant disease.

The physician should check blood pressure and examine the spine for scoliosis and the limbs for pseudarthroses. Head measurement often shows macrocephaly. Hearing and vision need to be assessed. The eye examination should include a check for proptosis and iris Lisch nodules. The optic disk should be examined for atrophy or papilledema. Short stature and precocious puberty are occasional findings. An examination for neurologic manifestations of tumors (eg, asymmetrical reflexes or spasticity) is important.
B. Laboratory Findings

Laboratory tests are not likely to be of value in asymptomatic patients. Selected patients require brain MRI with special cuts through the optic nerves to rule out optic glioma. Hypertension necessitates evaluation of renal arteries for dysplasia and stenosis. Cognitive and school achievement testing may be indicated. Scoliosis or limb abnormalities should be studied by appropriate roentgenograms such as an MRI scan of the spinal cord and roots.

Differential Diagnosis

Patients with McCune-Albright syndrome often have larger café-au-lait spots with precocious puberty, polyostotic fibrous dysplasia, and hyperfunctioning endocrinopathies. One or two café-au-lait spots are often seen in normal children. A large solitary café-au-lait spot is usually innocent, not neurofibromatosis type 1.

Complications

Seizures, deafness, short stature, early puberty, and hypertension occur in less than 25% of patients with neurofibromatosis. Optic glioma occurs in about 15%. Although the tumor may be apparent at an early age, it rarely causes functional problems and is usually nonprogressive. Patients have a slightly increased risk (5% life risk) for various malignancies. Other tumors may be benign but may cause significant morbidity and mortality because of their size and location in a vital or enclosed space.

Treatment

Genetic counseling is important. The risk to siblings is up to 50%. The disease may be progressive, with serious complications occasionally seen. Patients sometimes worsen during puberty or pregnancy. Genetic screening of family members is required. Annual or semiannual visits are important in the early detection of school problems or bony or neurologic abnormalities. The following parameters should be recorded at each annual visit:

1. Child’s development and progress at school
2. Visual symptoms, visual acuity, and funduscopy until age 7 years (to detect optic pathway glioma, glaucoma)
3. Head circumference (rapid increase might indicate tumor or hydrocephalus)
4. Height (to detect abnormal pubertal development)
5. Weight (to detect abnormal pubertal development)
6. Pubertal development (to detect delayed or precocious puberty due to pituitary or hypothalamic lesion)
7. Blood pressure (to detect renal artery stenosis or pheochromocytoma)
8. Cardiovascular examination (for congenital heart disease, especially pulmonary stenosis)
9. Evaluation of spine (for scoliosis and underlying plexiform neurofibromas)
10. Evaluation of the skin (for cutaneous, subcutaneous, and plexiform neurofibromas)
11. Examination of other systems, depending on specific symptoms

Multidisciplinary clinics at medical centers around the United States are excellent resources. Prenatal diagnosis is probably on the horizon, but the variability of manifestations (trivial to severe) will make therapeutic abortion an unlikely option. Chromosomal linkage studies are under way (chromosome 17q11.2). Information for lay people and physicians is available from the National Neurofibromatosis Foundation (http://www.nf.org).

2. Tuberous Sclerosis (Bourneville Disease)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Facial angiofibromas or subungal fibromas.
- Often hypomelanotic macules, gingival fibromas.
- Retinal hamartomas.
Cortical tubers or subependymal glial nodules, often calcified.
Renal angiomyolipomas.

General Considerations
Tuberous sclerosis is a dominantly inherited disease. Almost all patients have deletions on chromosome 9 (TSC1 gene) or 16 (TSC2 gene). The gene products hamartin and tuberin have tumor-suppressing effects. A triad of seizures, mental retardation, and adenoma sebaceum occurs in only 33% of patients. The disease was earlier thought to have a high rate of mutation. As a result of more sophisticated techniques such as MRI, parents formerly thought not to harbor the gene are now being diagnosed as asymptomatic carriers.

Like neurofibromatosis, tuberous sclerosis is associated with a wide variety of symptoms. The patient may be asymptomatic except for skin findings or may be devastated by severe infantile spasms in early infancy, by continuing epilepsy, and by mental retardation. Seizures in early infancy correlate with later mental retardation.

Clinical Findings
A. Symptoms and Signs

1. Dermatologic features—Skin findings bring most patients to the physician’s attention. Ninety-six percent of patients have one or more hypomelanotic macules, facial angiofibromas, ungual fibromas, or shagreen patches. Adenoma sebaceum, the facial skin hamartomas, may first appear in early childhood, often on the cheek, chin, and dry sites of the skin where acne is not usually seen. They often have a reddish hue. The off-white hypomelanotic macules are seen more easily in tanned or dark-skinned individuals than in those with lighter skin. The macules often are oval or “ash leaf” in shape and follow dermatomes. A Wood’s lamp (ultraviolet light) shows the macules more clearly, a great help in the light-skinned patient. In the scalp, poliosis (whitened hair) is the equivalent. In infancy, the presence of these macules accompanied by seizures is virtually diagnostic of the disease. Subungal or periungal fibromas are more common in the toes. Leathery, orange peel–like shagreen patches support the diagnosis. Café-au-lait spots are occasionally seen. Fibrous or raised plaques may resemble coalescent angiofibromas.

2. Neurologic features—Seizures are the most common presenting symptom. Five percent of patients with infantile spasms (a serious epileptic syndrome) have tuberous sclerosis. Thus any patient presenting with infantile spasms (and the parents as well) should be evaluated for this disorder. An imaging study of the CNS, such as a CT scan, may show calcified subependymal nodules; MRI may show dysmyelinating white matter lesions or cortical tubers. Virtually any kind of symptomatic seizure (eg, atypical absence, partial complex, and generalized tonic-clonic seizures) may occur.

3. Mental retardation—Mental retardation occurs in up to 50% of patients referred to tertiary care centers; the incidence is probably much lower in randomly selected patients. Patients with seizures are more prone to mental retardation or learning disabilities.

4. Renal lesions—Renal cysts or angiomyolipomas may be asymptomatic. Hematuria or obstruction of urine flow sometimes occurs; the latter requires operation. Ultrasonography of the kidneys should be done in any patient suspected of tuberous sclerosis, both to aid in diagnosis if lesions are found and to rule out renal obstructive disease.

5. Cardiopulmonary involvement—Rarely cystic lung disease may occur. Rhabdomyomas of the heart may be asymptomatic but can lead to outflow obstruction, conduction difficulties, and death. Chest radiographs and echocardiograms can detect these rare manifestations. Cardiac rhabdomyoma may be detected on prenatal ultrasound examination.

6. Eye involvement—Retinal hamartomas are often near the disk.

7. Skeletal involvement—Findings sometimes helpful in diagnosis are cystic rarefactions of the bones of the fingers or toes.

B. Diagnostic Studies

Plain radiographs may detect areas of thickening within the skull, spine, and pelvis, and cystic lesions in the hands and feet. Chest radiographs may show lung honeycomb. More helpful is CT scanning, which can show the virtually pathognomonic subependymal nodular calcifications and sometimes widened gyri or tubers and brain tumors. Contrast material may show the often classically located tumors near the interventricular foramen. Hypomyelinated lesions may be seen with MRI. Electroencephalography is helpful in delineating the presence of seizure discharges.

Treatment
Therapy is as indicated by underlying disease (eg, seizures and tumors of the brain, kidney, and heart). Skin lesions on the face may need dermabrasion or laser treatment. Genetic counseling emphasizes identification of the carrier. The risk of appearance in offspring if either parent is a carrier is 50%. The patient should be seen annually for counseling and reexamination in childhood. Identification of the chromosomes (9,16; TSC1 and TSC2 genes) may in the future make intrauterine diagnosis possible.
3. Encephalofacial Angiomatosis (Sturge-Weber Disease)

Sturge-Weber disease consists of a facial port wine nevus involving the upper part of the face (in the first division of cranial nerve V), a venous angiomatosis of the meninges in the occipitoparietal regions, and choroidal angioma. The syndrome has been described without the facial nevus (rare, type III, exclusive leptomeningeal angioma).

Clinical Findings

In infancy, the eye may show congenital glaucoma, or buphthalmos, with a cloudy, enlarged cornea. In early stages, the facial nevus may be the only indication, with no findings in the brain even on radiologic studies. The characteristic cortical atrophy, calcifications of the cortex, and meningeal angiomatosis may appear with time, solidifying the diagnosis.

Physical examination may show focal seizures or hemiparesis on the side opposite the cerebral lesion. The facial nevus may be much more extensive than the first division of cranial nerve V; it can involve the lower face, mouth, lip, neck, and even torso. Hemiatrophy of the opposite limbs may occur. Mental handicap may result from poorly controlled seizures. Late-appearing glaucoma and rarely CNS hemorrhage occur.

Radiologic studies may show calcification of the cortex; CT scanning may show this much earlier than plain radiographic studies. MRI often shows underlying brain involvement.

The EEG often shows depression of voltage over the involved area in early stages; later, epileptiform abnormalities may be present focally.

Treatment

Sturge-Weber disease is sporadic. Early control of seizures is important to avoid consequent developmental setback. If seizures do not occur, normal development can be anticipated. Careful examination of the newborn, with ophthalmologic assessment to detect early glaucoma, is indicated. Rarely, surgical removal of the involved meninges and the involved portion of the brain may be indicated, even hemispherectomy.

4. von Hippel-Lindau Disease (Retinocerebellar Angiomatosis)

von Hippel-Lindau disease is a rare, dominantly inherited condition with retinal and cerebellar hemangioblastomas; cysts of the kidneys, pancreas, and epididymis; and sometimes renal cancers. The patient may present with ataxia, slurred speech, and nystagmus due to a hemangioblastoma of the cerebellum or with a medullary spinal cord cystic hemangioblastoma. Retinal detachment may occur from hemorrhage or exudate in the retinal vascular malformation. Rarely a pancreatic cyst or renal tumor may be the presenting symptom.

The diagnostic criteria for the disease are a retinal or cerebellar hemangioblastoma with or without a positive family history, intra-abdominal cyst, or renal cancer.

CENTRAL NERVOUS SYSTEM DEGENERATIVE DISORDERS OF INFANCY & CHILDHOOD

The CNS degenerative disorders of infancy and childhood are characterized by arrest of psychomotor development and loss, usually progressive but at variable rates, of mental and
motor functioning and often of vision as well (Tables 23–20 and 23–21). Seizures are common in some disorders. Symptoms and signs vary with age at onset and primary sites of involvement of specific types.

These disorders are fortunately rare. An early clinical pattern of decline often follows normal early development. Referral for sophisticated biochemical testing is usually necessary before a definitive diagnosis can be made. Recently, many physicians have been involved in experimental bone marrow transplantation and enzyme replacement therapy for some of these disorders, with variable results. Patients with metachromatic leukodystrophy, Krabbe disease, and adrenoleukodystrophy are candidates for experimental bone marrow transplantation, but results are uncertain. Treatment of some lysosomal storage diseases, such as Gaucher disease, with enzyme replacement therapy has shown promising results.

ATAXIAS OF CHILDHOOD

1. Acute Cerebellar Ataxia

Acute cerebellar ataxia occurs most commonly in children aged 2–6 years. The onset is abrupt, and the evolution of symptoms is rapid. In about 50% of patients, a prodromal illness occurs with fever, respiratory or gastrointestinal symptoms, or an exanthem within 3 weeks of onset. Associated viral infections include varicella, rubella, mumps, rubella, echovirus infections, poliomyelitis, infectious mononucleosis, and influenza. Bacterial infections such as scarlet fever and salmonellosis have also been incriminated.

Clinical Findings

A. Symptoms and Signs

Ataxia of the trunk and extremities may be so severe that the child exhibits a staggering, reeling gait and inability to sit without support or to reach for objects; or he or she may show only mild unsteadiness. Hypotonia, tremor of the extremities, and horizontal nystagmus may be present. Speech may be slurred. The child is frequently irritable, and vomiting may occur.

There are no clinical signs of increased intracranial pressure. Sensory and reflex testing usually shows no abnormalities.

B. Laboratory Findings and Imaging

CSF pressure and protein and glucose levels are normal; slight lymphocytosis (≤ 30 cells/mL) may be present. Attempts should be made to identify the etiologic viral agent. CT scans are normal; MRI may show cerebellar postinfectious demyelinating lesions. The EEG may be normal or may show nonspecific slowing.

</tbody>
</table>

(continued)
Differential Diagnosis

Acute cerebellar ataxia must be differentiated from acute cerebellar syndromes due to phenytoin, phenobarbital, primidone, or lead intoxication. For phenytoin, the toxic level in serum is usually above 25 mcg/mL; for phenobarbital, above 50 mcg/mL; for primidone, above 14 mcg/mL. (See section on Seizure Disorders, earlier.) Papilledema, anemia, basophilic stippling of erythrocytes, proteinuria, typical radiographs, and elevated CSF protein are clinical clues to lead intoxication, which is confirmed by serum, urine, or hair lead levels. Polymyoclonus-opsoclonus syndrome with an occult neuroblastoma (see following section) occasionally begins as acute cerebellar ataxia.

In rare cases, acute cerebellar ataxia may be the presenting sign of acute bacterial meningitis or may be mimicked by corticosteroid withdrawal, vasculitides such as in polyarteritis nodosa, trauma, the first attack of ataxia in a metabolic disorder such as Hartnup disease, or the onset of acute disseminated encephalomyelitis or of multiple sclerosis. The history and physical findings may differentiate these disturbances, but appropriate laboratory studies are often necessary. For ataxias with more chronic onset and course, see the sections on spinocerebellar degeneration and the other degenerative disorders.

Treatment & Prognosis

Treatment is supportive. Corticosteroids have not been shown to be of benefit; IVIG has been used. Between 80% and 90% of children with acute cerebellar ataxia not secondary to drug toxicity recover without sequelae within 6–8 weeks. In the remainder, neurologic disturbances, including disorders of behavior and of learning, ataxia, abnormal eye movements, and speech impairment, may persist for months or years, and recovery may remain incomplete.

2. Polymyoclonus-Opsoclonus
Syndrome of Childhood (Infantile Myoclonic Encephalopathy, “Dancing Eyes-Dancing Feet” Syndrome)

The symptoms and signs of this syndrome are at first similar to those of acute cerebellar ataxia. Often of sudden onset, polymyoclonus-opsoclonus syndrome is characterized by severe incoordination of the trunk and extremities with lightning-like jerking or flinging movements of a group of muscles, causing the child to be in constant motion while awake. Extraocular muscle involvement results in sudden irregular eye movements (opsoclonus). Irritability and vomiting are often present, but there is no depression of level of consciousness. This syndrome occurs in association with viral infections and tumors of neural crest origin among other disorders. Immunologic mechanisms have been postulated. Usually no signs of increased intracranial pressure are present. CSF may show normal or mildly increased protein levels. Special techniques show increased CSF levels of plasmacytes and abnormal immunoglobulins. The EEG may be slightly slow, but when performed together with EMG, it shows no evidence of association between cortical discharges and the muscle movements. An assiduous search must be made to rule out tumor of neural crest origin by chest radiographs and CT, MRI, or ultrasound of the adrenal area as well as by assays of urinary catecholamine metabolites (vanillylmandelic acid and others) and cystathionine.

The symptoms respond variably to ACTH or to IVIG. Plasmapheresis has been successful. Usually the underlying neural crest tumor is benign (ganglioneuroblastoma); surgical excision may be the only oncologic therapy needed. Life span is determined by the biologic behavior of the tumor. The syndrome is usually self-limited but may be characterized by exacerbations and remissions, even after the removal of the neural crest tumor and without other evidence of its location.

recurrence, symptoms may reappear. Mild mental retardation may be a sequela.

3. Spinocerebellar Degeneration Disorders

Spinocerebellar degeneration disorders may be hereditary or may occur in sporadic fashion. Hereditary disorders include Friedreich ataxia, dominant hereditary ataxia, and a group of miscellaneous diseases.

A. Friedreich Ataxia

This is a recessive disorder characterized by onset of gait ataxia or scoliosis before puberty that becomes progressively worse. Reflexes, light touch, and position sensation are reduced. Dysarthria becomes progressively more severe. Cardiomyopathy usually develops, and diabetes mellitus occurs in 40% of patients, half of whom require insulin. Pes cavus typically is found. The GAA trinucleotide repeats on chromosome 9 can be used for laboratory diagnosis.

Treatment includes surgery for scoliosis and intervention as needed for cardiac disease and diabetes. Antioxidants may slow cardiac deterioration. Patients are usually confined to a wheelchair after age 20 years. Death occurs, usually from heart failure or dysrhythmias, in the third or fourth decade; some patients survive longer.

B. Dominant Ataxia

These diseases (in the past known as olivopontocerebellar atrophy, Holmes ataxia, Marie ataxia, and the like) occur with varying manifestations, even among members of the same family. Ataxia occurs at onset, and progression continues with ophthalmoplegias (in some patients), extrapyramidal syndromes, polynephropathy, and dementia. Several types have been found to be caused by CAG trinucleotide repeats. Levodopa may ameliorate rigidity and bradykinesia, but no other therapy is available. Only 10% of patients experience onset in childhood, and the course in these patients is often more rapid.

C. Miscellaneous Hereditary Ataxias

Associated findings permit identification of these recessive disorders. These include ataxia-telangiectasia (telangiectasia and immune defects; see below); Wilson disease (Kayser-Fleischer rings); Rfusm disease (ichthyosis, cardiomyopathy, retinitis pigmentosa, and large nerves); Rett syndrome (regression to autism at age 7–18 months in girls, loss of use of hands, and progressive failure of brain growth); and abetalipoproteinemia (infantile diarrhea, acanthocytosis, and retinitis pigmentosa). Gluten sensitivity may cause ataxia. Patients with juvenile and chronic gangliosidoses and some hemolytic anemias and long-term survivors of Chédiak-Higashi disease may develop spinocerebellar degeneration. Idiopathic familial ataxia is called Behr syndrome. Neuropathies such as Charcot-Marie-Tooth disease produce ataxia.

ATAxia-TELangIectasIa

(LOUIs-bar sYndrome)

Ataxia-telangiectasia is a multisystem disorder inherited as an autosomal recessive trait. It is characterized by progres-
sive ataxia; telangiectasia of the bulbar conjunctivae, external ears, nares, and (later) other body surfaces, appearing in the third to sixth year; and recurrent respiratory, sinus, and ear infections. Ocular dyspraxia, slurred speech, choreoathetosis, hypotonia and areflexia, and psychomotor and growth retardation may be present. Endocrinopathies are common. Nerve conduction velocities may be reduced. The entire nervous system may be affected in late stages of the disease. A spectrum of involvement may be seen in the same family. Immunodeficiencies of IgA and IgE are common (see Chapter 31), and the incidence of certain cancers is high. Elevated serum α-fetoprotein is a screen for this disease.

### Clinical Findings

#### A. Symptoms and Signs

Chorea, or rapid involuntary movements of the limbs and face, is the hallmark physical finding. In addition to the jerky incoordinate movements, the following are noted: emotional lability, waxing and waning (“milkmaid’s”) grip, darting tongue, “spooning” of the extended hands and their tendency to pronate, and knee jerks slow to return from the extended to their prestimulus position (“hung up”). Seizures, while uncommon, may be masked by choreic jerks.

#### B. Laboratory Findings

Anemia, leukocytosis, and an increased erythrocyte sedimentation rate and C-reactive protein may be present. The antistreptolysin O or anti-DNase titer (or both) may be elevated, and C-reactive protein present. Throat culture is sometimes positive for group A β-hemolytic streptococci.

ECG and echocardiography are often essential to detect cardiac involvement. Antineuronal antibodies are present in most patients but are not specific for this disease. Specialized radiologic procedures (MRI and SPECT) may show basal ganglia abnormalities.

### Differential Diagnosis

The diagnosis of Sydenham chorea is usually not difficult. Tics, drug-induced extrapyramidal syndromes, Huntington chorea, and hepatolenticular degeneration (Wilson disease), as well as other rare movement disorders, can usually be ruled out on historical and clinical grounds. Immunologic linkages among chorea, tics, and obsessive-compulsive disorder are being studied in pediatric patients. Stroke is a rare cause for unilateral chorea. Other causes of chorea can be ruled out by laboratory tests, such as antinuclear antibody for lupus, thyroid screening tests, serum calcium for hypocalcemia, and immunologic and virologic tests for (rare) HIV, parvovirus B19, and Epstein-Barr virus infection.

### Treatment

There is no specific treatment. Dopaminergic blockers such as haloperidol (0.5 mg to 3–6 mg/d) and pimozide (2–10 mg/d) have been used. Parkinsonian side effects such as rigidity and masked facies, and with high doses tardive dyskinesia, rarely occur in childhood. Other drugs have been used with success in individual cases; these include the anticonvulsant sodium valproate (50–60 mg/kg/d in divided doses) and prednisone (0.5–2 mg/kg/d in divided doses). IVIG has been successful in severe cases. Emotional lability and depression sometimes warrant administration of antidepressants. All patients should be given antistreptococcal rheumatic fever prophylaxis, possibly through childhood age.
2. Tics (Habit Spasms)

Clinical Findings

Tics, or habit spasms, are quick repetitive but irregular movements, often stereotyped, and briefly suppressible. Coordination and muscle tone are not affected. A psychogenic basis is seldom discernible. Transient tics of childhood (12–24% incidence in school-aged children) last from 1 month to 1 year and seldom need treatment. Many children with tics have a history of encephalopathic past events, neurologic soft signs, and school problems. Facial tics such as grimaces, twitches, and blinking predominate, but the trunk and extremities are often involved and twisting or flinging movements may be present. Vocal tics are less common.

Tourette syndrome is characterized by multiple fluctuating motor and vocal tics with no obvious cause lasting more than 1 year. Tics evolve slowly, new ones being added to or replacing old ones. Coprolalia and echolalia are relatively infrequent. Partial forms are common. The usual age at onset is 2–15 years, and the familial incidence is 35–50%.

The disorder occurs in all ethnic groups. Tourette syndrome may be triggered by stimulants such as methylphenidate and dextroamphetamine. An imbalance of or hypersensitivity to neurotransmitters, especially dopaminergic and adrenergic, has been hypothesized.

In mild cases, tics are self-limited, and when disregarded disappear. When attention is paid to one tic, it may disappear only to be replaced by another that is often worse. If the tic and its underlying anxiety or compulsive neuroses are severe, psychiatric evaluation and treatment are needed.

Important comorbidities are attention-deficit/hyperactivity disorder and obsessive-compulsive disorder. Learning disabilities, sleep difficulties, anxiety states, and mood swings are also common. Medications such as methylphenidate and dextroamphetamine should be carefully titrated to treat attention-deficit/hyperactivity disorder and avoid worsening tics. Fluoxetine and clomipramine may be useful for obsessive-compulsive disorder and rage episodes in patients with tics.

Treatment

The most effective medications for treating Tourette syndrome are dopamine blockers; however, many pediatric patients can manage without drug treatment. Medications are generally reserved for patients with disabling symptoms; treatment may be relaxed or discontinued when the symptoms abate (Table 23–22). Nonpharmacologic treatment of Tourette syndrome includes education of patients, family members, and school personnel. In some cases, restructuring the school environment to prevent tension and teasing may be necessary. Supportive counseling, either at or outside school, should be provided. Medications usually do not eradicate the tics. The goal of treatment should be to reduce

the tics to tolerable levels without inducing undesirable side effects. Medication dosage should be increased at weekly intervals until a satisfactory response is obtained. Often a single dose at bedtime is sufficient. The two neuroleptic agents used most often are pimozide and risperidone. Sleepiness and weight gain are the most common side effects; rare are prolonged QT interval (ECG), akathisia, and tardive dyskinesia. Clonidine, guanfacine, and dopamine modulators have been used in individual patients with some success. Sometimes these agents are used in combination (eg, clonidine with pimozide). IVIG has been unsuccessful.

Sydenham chorea is a well-documented pediatric autoimmune disorder associated with streptococcal infections (pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection; PANDAS). Patients with tic disorders occasionally have obsessive-compulsive disorder precipitated or exacerbated by streptococcal infections. Less definite (much less frequent) are tic flare-ups with streptococcal infection. Active prospective antibody (anti-neuronal and anti-streptococcal) and clinical studies are in progress. Research centers have used experimental treatments (IVIG, plasmapheresis, and corticosteroids) in severe cases. At present, most patients with a tic do not worsen with group A streptococcal infection; PANDAS. Patients often grow out of this disease in one or two decades. Nonkinesigenic dyskinesia is often secondary to an identifiable brain lesion, less or not responsive to medications, and nongenetic.

Disorders of ion channels underlie many of the genetic cases; some cases are linked to epilepsy and hemiplegic migraine. Chromosome loci are known.

The diagnosis of chronic persistent dystonia (sometimes 1-dopa–responsive; DYT5) may be aided by spinal fluid neurotransmitter (DYT5) and genetic chromosome studies: DYT1 is the most common. Rarely, dyskinesia (eg, dystonia) may be precipitated by fever. Persistent chorea (rarely) may be a benign lifelong genetic disease.

**4. Tremor**

The most common cause of persisting tremors in childhood is essential tremor. Of those with this lifelong malady, 4.6% have onset in childhood (2–16 years). A genetic dominant inheritance is probable; 20–80% afflicted report a relative with tremors. Tremor, a mild fine motor and cosmetic handicap, is worsened by anxiety, fatigue, stress, physical activity, and caffeine, and transiently improved by alcohol. Comorbidities include attention-deficit/hyperactivity disorder, dystonia, and possibly Tourette syndrome. Hand/arm tremor is the major manifestation; voice and head tremors are rare. Sometimes, “shuddering attacks” in infancy are a forerunner.

Laboratory studies are normal. Progression is usually minimal. Some patients develop other movement disorders.
CHAPTER 23

Infections of the CNS are among the most common neurologic disorders encountered by pediatricians. Although infections are among the CNS disorders most amenable to treatment, they also have a very high potential for causing catastrophic destruction of the nervous system. It is imperative for the clinician to recognize infections early in order to treat and prevent massive tissue destruction.

Clinical Findings

A. Symptoms and Signs

Patients with CNS infections, whether caused by bacteria, viruses, or other microorganisms, present with similar manifestations. Systemic signs of infection include fever; malaise; and impaired heart, lung, liver, or kidney function. General features suggesting CNS infection include headache, stiff neck, fever or hypothermia, changes in mental status (including hyperirritability evolving into lethargy and coma), seizures, and focal sensory and motor deficits. Meningeal irritation is manifested by the presence of Kernig and Brudzinski signs. In very young infants, signs of meningeal irritation may be absent, and temperature instability and hypothermia are often more prominent than fever. In young infants, a bulging fontanelle and an increased head circumference are common. Papilledema may eventually develop, particularly in older children and adolescents. Cranial nerve palsies may develop acutely or gradually during the course of neurologic infections. No specific clinical sign or symptom is reliable in distinguishing bacterial infections from infections caused by other microbes.

During the initial clinical assessment, conditions that predispose the patient to infection of the CNS should be sought. Infections involving the sinuses or other structures in the head and neck region can result in direct extension of infection into the intracranial compartment. Open head injuries, recent neurosurgical procedures, immunodeficiency, and the presence of a mechanical shunt may predispose to intracranial infection.

B. Laboratory Findings

When CNS infections are suspected, blood should be obtained for a complete blood count, general chemistry panel, and culture. Most important, however, is obtaining CSF. In the absence of focal neurologic deficits or signs of brainstem herniation, CSF should be obtained immediately from any patient in whom serious CNS infection is suspected. When papilledema or focal motor signs are present, a lumbar puncture may be delayed until a neuroimaging procedure has been done to exclude space-occupying lesions. Treatment must be started even if lumbar puncture is delayed. It is generally safe to obtain spinal fluid from infants with nonfocal neurologic examination even if the fontanelle is bulging. Spinal fluid should be examined for the presence of red and white blood cells, protein concentration, glucose concentration, bacteria, and other microorganisms; a sample should be cultured. In addition, serologic, immunologic, and nucleic acid detection (PCR) tests may be performed on the spinal fluid in an attempt to identify the specific organism. Spinal fluid that contains a high proportion of polymorphonuclear leukocytes, a high protein concentration, and a low glucose concentration strongly suggests bacterial infection (see Chapter 40). CSF containing predominantly lymphocytes, a high protein concentration, and a low glucose concentration suggests infection with mycobacteria, fungi, uncommon bacteria, and some viruses such as lymphocytic choriomeningitis virus, herpes simplex virus, mumps virus, and arboviruses (see Chapters 38 and 41). CSF that contains a high proportion of lymphocytes, normal or only slightly elevated protein concentration, and a normal glucose concentration is most suggestive of viral infections, although partially treated bacterial meningitis and parameningeal infections may also result in this type of CSF formula. Typical CSF findings in a variety of infectious and inflammatory disorders are shown in Table 23–2.

In some cases, brain biopsy may be needed to identify the presence of specific organisms and clarify the diagnosis. Herpes simplex virus infections can be confirmed using the PCR test to assay for herpes DNA in spinal fluid. This test has 95% sensitivity and 99% specificity. Brain biopsy may be needed to detect the rare PCR-negative case of herpes simplex and various parasitic infections, or in a suspected noninfectious cause with ambiguous spinal fluid findings (eg, vasculitis).

C. Imaging

Neuroimaging with CT and MRI scans may be helpful in demonstrating the presence of brain abscess, meningeal
inflammation, or secondary problems such as venous and arterial infarctions, hemorrhages, and subdural effusions when these are suspected. In addition, these procedures may identify sinus or other focal infections in the head or neck region that are related to the CNS infection. CT bone windows may demonstrate bony abnormalities such as basilar fractures.

EEGs may be helpful in the assessment of patients who have had seizures at the time of presentation. The changes are often nonspecific and characterized by generalized slowing. In some instances, such as herpes simplex virus or focal enterovirus infection, lateralized epileptiform discharges may be seen early in the course and may be one of the earliest laboratory abnormalities to suggest the diagnosis. EEGs may also show focal slowing over regions of infarcts or (rare) abscesses.

**BACTERIAL MENINGITIS**

Bacterial infections of the CNS may present acutely (symptoms evolving rapidly over 1–24 hours), subacutely (symptoms evolving over 1–7 days), or chronically (symptoms evolving over more than 1 week). Diffuse bacterial infections involve the leptomeninges, superficial cortical structures, and blood vessels. Although the term *meningitis* is used to describe these infections, it should not be forgotten that the brain parenchyma is also inflamed and that blood vessel walls may be infiltrated by inflammatory cells that result in endothelial cell injury, vessel stenosis, and secondary ischemia and infarction. Overall clinical characteristics of bacterial meningitis (and viral meningoencephalitis) are outlined in Table 23–23.

Pathologically, the inflammatory process involves all intracranial structures to some degree. Acutely, this inflammatory process may result in cerebral edema or impaired CSF flow through and out of the ventricular system, resulting in hydrocephalus.

▶ **Treatment**

**A. Specific Measures**

(See also Chapters 37, 38, and the section on bacterial infections in Chapter 40.)

While awaiting the results of diagnostic tests, the physician should start broad-spectrum antibiotic coverage as noted in the following discussion. After specific organisms are identified, antibiotic therapy can be tailored based on antibiotic sensitivity patterns. Bacterial meningitis in children younger than age 3 months is treated initially with cefotaxime (or ceftriaxone if the child is older than age 1 month) and ampicillin; the latter agent is used to treat *Listeria* and enterococci infections, which rarely affect older children. Children older than age 3 months are given ceftriaxone, cefotaxime, or ampicillin plus gentamicin. If *Streptococcus pneumoniae* cannot be ruled out by the initial Gram stain, vancomycin or rifampin is added until cultures are reported, because penicillin-resistant pneumococci are common in the United States. Therapy may be narrowed when organism sensitivity allows. Duration of therapy is 7 days for meningococcal infections, 10 days for *Haemophilus influenzae* or pneumococcal infection, and 14–21 days for other organisms. Slow clinical response or the occurrence of complications may prolong the need for therapy.

**B. General and Supportive Measures**

Children with bacterial meningitis are often systemically ill. The following complications should be looked for and treated aggressively: hypovolemia, hypoglycemia, hyponatremia, acidosis, septic shock, increased intracranial pressure, seizures, disseminated intravascular coagulation, and metastatic infection (eg, pericarditis, arthritis, or pneumonia). Children should initially be monitored closely (cardiorespiratory monitor, strict fluid balance and frequent urine specific gravity assessment, daily weights, and neurologic assessment every few hours), not fed until neurologically very stable, isolated until the organism is known, rehydrated with isotonic solutions until euvolemic, and then given intravenous fluids containing dextrose and sodium at no more than maintenance rate (assuming no unusual losses occur).

▶ **Complications**

Abnormalities of water and electrolyte balance result from either excessive or insufficient production of antidiuretic hormone and require careful monitoring and appropriate adjustments in fluid administration. Monitoring serum sodium every 8–12 hours during the first 1–2 days, and urine sodium if the inappropriate secretion of antidiuretic hormone is suspected, usually uncovers significant problems.
Seizures occur in up to 30% of children with bacterial meningitis. Seizures tend to be most common in neonates and less common in older children. Persistent focal seizures or focal seizures associated with focal neurologic deficits strongly suggest subdural effusion, abscess, or vascular lesions such as arterial infarct, cortical venous infarcts, or dural sinus thrombosis. Because generalized seizures in a metabolically compromised child may have severe sequelae, early recognition and therapy are critical; some practitioners prefer phenytoin for acute management because it is less sedating than phenobarbital.

Subdural effusions occur in as many as 50% of young children with *S. pneumoniae* meningitis. Subdural effusions are often seen on CT scans of the head during the course of meningitis. They do not require treatment unless they are producing increased intracranial pressure or progressive mass effect. Although subdural effusions may be detected in children who have persistent fever, such effusions do not usually have to be sampled or drained if the infecting organism is *H. influenzae*, meningococcus, or pneumococcus. These are usually sterilized with the standard treatment duration, and slowly waning fever during an otherwise uncomplicated recovery may be followed clinically. Under any other circumstance, however, aspiration of the fluid for documentation of sterilization or for relief of pressure should be considered. Interestingly, prognosis is not worsened by subdural effusions.

Cerebral edema can participate in the production of increased intracranial pressure, requiring treatment with dexamethasone, osmotic agents, diuretics, or hyperventilation; continuous pressure monitoring may be needed.

Long-term sequelae of meningitis result from direct inflammatory destruction of brain cells, vascular injuries, or secondary gliosis. Focal motor and sensory deficits, visual impairment, hearing loss, seizures, hydrocephalus, and a variety of cranial nerve deficits can result from meningitis. Sensorineural hearing loss in *H. influenzae* meningitis occurs in approximately 5–10% of patients during long-term follow-up. Recent studies have suggested that early addition of dexamethasone to the antibiotic regimen may modestly decrease the risk of hearing loss in some children with bacterial meningitis (see Chapter 40).

In addition to the variety of disorders mentioned earlier in this section, some patients with meningitis have mental retardation and severe behavioral disorders that limit their function at school and later performance in life.

**BRAIN ABSCESS**

#### Clinical Findings

Patients with brain abscess often appear to have systemic illness similar to patients with bacterial meningitis, but in addition they show signs of focal neurologic deficits, papilledema, and other evidence of increased intracranial pressure or a mass lesion. Symptoms may be present for a week or more; children with bacterial meningitis usually present within a few days. Conditions predisposing to development of brain abscess include penetrating head trauma; chronic infection of the middle ear, mastoid, or sinuses (especially the frontal sinus); chronic dental or pulmonary infection; cardiovascular lesions allowing right-to-left shunting of blood (including arteriovenous malformations); and endocarditis. Sinus infections more characteristically cause subdural-epidural, orbital and forehead abscesses or empyemas, or cellulitis rather than intrabrain abscesses. Recent reports have identified a predisposition to brain abscess in patients with congenital heart disease and acute immunosuppression, with a fungal cause in the latter, and *Citrobacter* infection in infants.

When brain abscess is strongly suspected, a neuroimaging procedure such as CT or MRI scans with contrast enhancement should be done prior to lumbar puncture. (CT scan can miss an epidural collection.) If a brain abscess is identified, lumbar puncture may be dangerous and rarely alters the choice of antibiotic or clinical management since the CSF abnormalities usually reflect only parameningeal inflammation or are often normal. With spread from contiguous septic foci, streptococci and anaerobic bacteria are most common. Staphylococci most often enter from trauma or spread from distant or occult infections. Enteric organisms may form an abscess from chronic otitis. Unfortunately, cultures from a large number of brain abscesses remain negative.

The diagnosis of brain abscess is based primarily on a strong clinical suspicion and confirmed by a neuroimaging procedure. Strongly positive inflammatory markers (erythrocyte sedimentation rate, C-reactive protein) are useful in screening. Normal results would be unlikely in patients with brain abscess. EEG changes are nonspecific but frequently demonstrate focal slowing in the region of brain abscess.

#### Differential Diagnosis

Differential diagnosis of brain abscess includes any condition that produces focal neurologic deficits and increased intracranial pressure, such as neoplasms, subdural effusions, cerebral infarctions, and certain infections (herpes simplex, cysticercosis, and toxocariasis).

#### Treatment

Initial therapy for infection from presumed contiguous foci uses penicillin and metronidazole. Cefotaxime is a good alternative to penicillin, especially if enteric organisms are suspected. Enteric organisms are also often susceptible to trimethoprim–sulfamethoxazole.Suspicion of infection by staphylococci, or their recovery from an aspirate, should be treated with nafcillin or vancomycin (for discussion of methicillin-resistant *Staphylococcus aureus* [MRSA], see Chapter 37). Treatment may include neurologic consulta-
tion and anticonvulsant and edema therapy if necessary. In their early stages, brain abscesses are areas of focal cerebritis and can be “cured” with antibiotic treatment alone. Encapsulated abscesses require surgical drainage.

**Prognosis**

The surgical mortality rate in the treatment of brain abscess is lower than 5%. Untreated cerebral abscesses lead to irreversible tissue destruction and may rupture into the ventricle, producing catastrophic deterioration in neurologic function and death. Because brain abscesses are often associated with systemic illness and systemic infections, the death rate is frequently high in these patients.

**VIRAL INFECTIONS**

Viral infections of the CNS can involve primarily meninges (meningitis) (see Chapter 38) or cerebral parenchyma (encephalitis) (see Table 23–23). All patients, however, have some degree of involvement of both the meninges and cerebral parenchyma (meningoencephalitis). Many viral infections are generalized and diffuse, but some viruses, notably herpes simplex and some enteroviruses, characteristically cause prominent focal disease. Focal cerebral involvement is clearly evident on neuroimaging procedures. Some viruses have an affinity for specific CNS cell populations. Poliovirus and other enteroviruses can selectively infect anterior horn cells (poliomyelitis) and some intracranial motor neurons.

Although most viral infections of the nervous system have an acute or subacute course in childhood, chronic infections can occur. Subacute sclerosing panencephalitis, for example, represents a chronic indolent infection caused by altered measles virus and is characterized clinically by progressive neurodegeneration and seizures.

Inflammatory reactions within the nervous system may occur during the convalescent stage of systemic viral infections. Parainfectious or postinfectious inflammation of the CNS results in several well-recognized disorders: acute disseminated encephalomyelitis (ADEM; 25% of encephalitis), transverse myelitis, optic neuritis, polyneuritis, and Guillain-Barré syndrome. MRI findings in ADEM are distinctive: demyelinating lesions, seen on T2 and FLAIR images, are key to the diagnosis. Small and large white matter lesions can mimic findings in multiple sclerosis (MS) but, unusually for MS, may involve gray matter such as cortex, basal ganglia, especially thalamus. Radiologic changes are usually florid when the patient is first seen but occasionally emerge only days to weeks later. Thus serial or repeat scans may be necessary.

Corticosteroids are beneficial. Current practice is to administer massive doses over 5 days, followed by tapering of the dosage over 2–4 weeks. (Older studies used 2–4 mg/kg/d; no comparative dose studies are available.) In refractory patients, IVIG or plasmapheresis (or both) may be effective. Rarely, ADEM relapses (biphasic acute disseminated encephalomyelitis; biDEM or BDEM). Recurrence more than 3 months after treatment should raise strong suspicion of MS. Congenital viral infections can also affect the CNS. CMV, herpes simplex virus, varicella and (rare now, because of immunization) rubella virus are the most notable causes of viral brain injury in utero.

Treatment of CNS viral infections is usually limited to symptomatic and supportive measures, except for herpes simplex virus: Acyclovir is utilized in some patients with varicella-zoster virus infections of the CNS. West Nile virus, new in the United States, is an arthropod-borne flavivirus. It is found in mosquitoes, birds, and horses, and in 1991 accounted for 27% of hospitalized patients with encephalitis and muscle weakness in New York. Fourteen percent had encephalitis alone, and 6% had aseptic meningitis. CSF antibody studies and PCR (57% positive for viral RNA) were diagnostic aids. The infection is now endemic as far as the western United States, particularly in California.

This disease is often asymptomatic or mild in pediatric patients; paralysis and death occur mostly in the elderly.

**ENCEPHALOPATHY OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION**

Neurologic syndromes associated directly with HIV infection include subacute encephalitis, meningitis, myelopathy, polyneuropathy, and myositis. In addition, secondary opportunistic infections of the CNS occur in patients with HIV-induced immunosuppression. *Pneumocystis*, *Toxoplasma*, and CMV infections are particularly common. Progressive multifocal leukoencephalopathy, a secondary papillomavirus infection, and herpes simplex and varicella-zoster infections also occur frequently in patients with HIV infection. Various fungal (especially cryptococcal), mycobacterial, and bacterial infections have been described.

Neurologic abnormalities in these patients can also be the result of noninfectious neoplastic disorders. Primary CNS lymphoma and metastatic lymphoma to the nervous system are the most frequent neoplasms of the nervous system in these patients. See Chapters 31, 37, and 39 for diagnosis and management of HIV infection.

**OTHER INFECTIONS**

A wide variety of other microorganisms, including *Toxoplasma*, mycobacteria, spirochetes, rickettsiae, amoebae, and mycoplasmas, can cause CNS infections. CNS involvement in these infections is usually secondary to systemic infection or other predisposing factors. Appropriate cultures and serologic testing are required to confirm infections by these organisms. Parenteral antimicrobial treatment for these infections is discussed in Chapter 37.
CHAPTER 23

NONINFECTIOUS INFLAMMATORY DISORDERS OF THE CENTRAL NERVOUS SYSTEM

The differential diagnosis of bacterial, viral, and other microbial infections of the CNS includes disorders that cause inflammation but for which no specific causal organism has been identified. Sarcoidosis, Behçet disease, systemic lupus erythematosus, other collagen-vascular disorders, and Kawasaki disease are examples. In these disorders, CNS inflammation usually occurs in association with characteristic systemic manifestations that allow proper diagnosis. Management of CNS involvement in these disorders is the same as the treatment of the systemic illness.

OTHER PARAINFECTIOUS ENCEPHALOPATHIES

In association with systemic infections or other illnesses, CNS dysfunction may occur in the absence of direct CNS inflammation or infection. Reye syndrome is a prominent example of this type of encephalopathy that often occurs in association with varicella virus or other respiratory or systemic viral infections. In Reye syndrome, cerebral edema and cerebral dysfunction occur, but there is no evidence of any direct involvement of the nervous system by the associated microorganism or inflammation. Cerebral edema in Reye syndrome is accompanied by liver dysfunction and fatty infiltration of the liver. As a result of efforts to discourage use of aspirin in childhood febrile illnesses, the number of patients with Reye syndrome has markedly decreased. The precise relationship, however, between aspirin and Reye syndrome is unclear.

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) can begin in childhood; 2–5% of individuals with MS have symptom onset before age 16 years. Formation of a Pediatric MS Study Group led to a supplementary issue of Neurology, summarizing pediatric MS and related disorders. (See Krupp and Hertz citation, included in the references below.) Essential points follow:

- Multiple sclerosis starts with clinical isolated symptoms (CSI) of CNS demyelination. Examples include optic neuritis; transverse myelitis; or brainstem, cerebellar, or hemispheric dysfunction, without fever or encephalopathy (whereas ADEM usually has both).
- Atypical clinical features (think of other diagnoses) include fever and involvement of the peripheral nervous system or other organ systems. Aberrant (for MS) laboratory results might include elevated erythrocyte sedimentation rate or marked CSF pleocytosis.
- A diagnosis of MS demands multiple episodes of CNS demyelination, separated in time and space. MRI (many fine-tuned criteria) and spinal fluid changes (oligoclonal bands, IgG index) are key laboratory tests.
- Differential diagnosis includes especially ADEM. Excellent tables, examples, and criteria abound in the supplementary issue of Neurology. Many other infections, metabolic disorders, and degenerative diseases can mimic MS.
- Acute treatment (mainly corticosteroids) and prevention or modulation of relapses is extrapolated from adult studies; pediatric trials are in their infancy.

SYNDROMES PRESENTING AS ACUTE FLACCID PARALYSIS

Flaccid paralysis evolving over hours or a few days suggests involvement of the lower motor neuron complex (see section on Floppy Infant Syndrome, later). Anterior horn cells (spinal cord) may be involved by viral infection (paralytic poliomyelitis) or by paraviral or postviral immunologically mediated disease (acute transverse myelitis). The nerve trunks (polyneu- ritis) may be diseased as in Guillain-Barré syndrome or affected by toxins (diphtheria or porphyria). The neuromuscular junction may be blocked by tick toxin or botulinum toxin. The paralysis rarely will be due to metabolic (periodic paralysis) or inflammatory muscle disease (myositis). A lesion compressing the spinal cord must be ruled out. The back often is tender to percussion at that site. Plain films may show disk or bone erosion; MRI, a displaced or compressed spinal cord. Several examples with pertinent discussions are included in a recent issue of Pediatrics in Review (2007, volume 28; see references at the end of this section).

Clinical Findings

A. Symptoms and Signs

Features assisting diagnosis are age, a history of preceding or waning illness, the presence (at time of paralysis) of fever, rapidity of progression, cranial nerve findings, and sensory findings (Table 23–24). The examination may show long tract findings (pyramidal tract), causing increased reflexes and a positive Babinski sign. The spinohalamic tract may be interrupted, causing loss of pain and temperature. Back pain, even tenderness to percussion, may occur, as well as bowel and bladder incontinence. Often the paralysis is ascending, symmetrical, and painful (muscle tenderness or myalgia). Laboratory findings occasionally are diagnostic.

B. Laboratory Findings (See Table 23–24)

Examination of CSF is helpful. Imaging studies of the spinal column (plain radiographs) and spinal cord (MRI) are occasionally essential. Viral cultures (CSF, throat, and stool) and titers aid in diagnosing poliomyelitis. A high sedimentation rate may suggest tumor or abscess; the presence of antinuclear antibody may suggest lupus arteritis. EMG and nerve conduction velocity can be helpful in diagnosing polyneuropathy. Nerve conduction is usually slowed after 7–10 days. Findings in botulism and tick-bite paralysis can be specific and diagnostic. Rarely, elevation of muscle enzymes or even myoglobinuria may aid in diagnosis of myopathic paralysis. Porphyrin urine studies and heavy-metal assays (arsenic, thallium, and lead) can reveal those rare toxic causes of polyneuropathic paralysis.

Differential Diagnosis

The child who has been well and becomes paralyzed often has polynuertitis. Acute transverse myelitis sometimes occurs in an afebrile child. The child who is ill and febrile at the time of paralysis often has acute transverse myelitis or poliomyelitis. Acute epidural spinal cord abscess (or other compressive lesion) must be ruled out. Poliomyelitis is very rare among the immunized population in the United States. Enterovirus 71 and West Nile disease are two new causes. Paralysis due to tick bites occurs seasonally (spring and summer). The tick is usually found in the occipital hair. Removal is curative.

Paralysis due to botulinum toxin occurs most commonly in those younger than age 6 months (see Chapter 40). Intravenous drug abuse can lead to myelitis and paralysis. Furthermore, chronic myelopathy occurs with two human immunodeficiency virus infections: HTLVI and HTLV-III (now called HIV-1).

Complications

A. Respiratory Paralysis

Early and careful attention to oxygenation is essential. Administration of oxygen, intubation, mechanical respira- tory assistance, and careful suctioning of secretions may be required. Increasing anxiety and a rise in diastolic and systolic blood pressures are early signs of hypoxia. Cyanosis is a late sign. Deteriorating spirometric findings (forced expiratory volume in 1 second and total vital capacity) may indicate the need for controlled intubation and respiratory support. Blood gases (usually late changes with increased CO₂ and decreased O₂) can aid decisions.

B. Infections

Pneumonia is common, especially in patients with respira- tory paralysis. Antibiotic therapy is best guided by results of cultures. Bladder infections occur when an indwelling cathe- ter is required because of bladder paralysis. Recovery from myelitis may be delayed by urinary tract infection.

C. Autonomic Crisis

This may be a cause of death in Guillain-Barré syndrome. Strict attention to vital signs to detect and treat hypotension or hypertension and cardiac arrhythmias in an intensive care setting is advisable, at least early in the course and in severely ill patients.

Treatment

Most of these syndromes have no specific treatment. Ticks causing paralysis must be removed. Other therapies include the use of erythromycin in Mycoplasma infections and botu- lism immune globulin in infant botulism. Recognized asso- ciated disorders (eg, endocrine, neoplastic, or toxic) should...

be treated by appropriate means. Supportive care also involves pulmonary toilet, adequate fluids and nutrition, bladder and bowel care, prevention of decubitus ulcers, and in many cases, psychiatric support.

A. Corticosteroids

These agents are believed by most to be of no benefit in Guillain-Barré syndrome. Autonomic symptoms (eg, hypertension) in polyneuritis may require treatment.

B. Plasmapheresis, Intravenous Immunoglobulin

Plasma exchange or IVIG has been beneficial in moderate or severe cases of Guillain-Barré syndrome. Some clinicians use inability to ambulate as a criterion to use IVIG.

C. Physical Therapy

Rehabilitative measures are best instituted when acute symptoms have subsided and the patient is stable.

D. Antibiotics

Appropriate antibiotics and drainage are required for epidural abscess.

</table>

aAMAN is acute motor axonal neuropathy (uncommon variant in the United States).

AIDP, acute inflammatory demyelinating neuropathy; CMV, cytomegalovirus; CSF, cerebrospinal fluid; EBV, Ebstein-Barr virus; EMG, electromyogram; EV-71, enterovirus 71; GI, gastrointestinal; IVIG, intravenous immune globulin; MRI, magnetic resonance imaging; PMN, polymorphonuclear neutrophil; SIDS, sudden infant death syndrome.

Muscle Biopsy

Properly executed (by open biopsy or by using the Bergstrom muscle biopsy needle), this procedure is usually helpful. Histochemical techniques, histogram analysis of muscle fiber types and sizes, and electron microscopy are offering new classifications of the myopathies. Findings common to the muscular dystrophies include variation in the size and shape of muscle fibers, increase in connective tissue, interstitial infiltration of fatty tissue, degenerative changes in muscle fibers, and central location of nuclei.

Dystrophin is a normal intracellular plasma membrane protein in muscle, the gene product missing in Duchenne and Becker muscular dystrophies. Staining the muscle for dystrophin aids in differentiating Duchenne and Becker muscular dystrophies; dystrophin is absent in Duchenne muscular dystrophy and reduced in Becker muscular dystrophy. Electrophoresis can confirm whether the dystrophin is absent or present in small amounts and whether there is a qualitative difference from normal dystrophin, the latter two patterns being characteristic of Becker muscular dystrophy.

Genetic Testing & Carrier Detection

Previously, detection of carriers for Duchenne muscular dystrophy (mothers and sisters of affected boys) rested on creatine kinase elevations (two thirds of patients will have this finding); physical findings of mild dystrophy (large calves and muscle weakness); abnormal muscle EMGs; or biopsy results. All are unreliable for diagnostic purposes.

DNA probes are now available for carrier detection and prenatal diagnosis of Duchenne and Becker muscular dystrophies. Deletions are often (60%) found on the short arm of the X chromosome; it is postulated that all patients and most mothers will show deletions when sufficient probes are developed to search the whole Duchenne genome (perhaps 4000 kb in length).

Amplification of DNA by the PCR test can detect the deletion. Moreover, this technique plus Southern blot analysis can detect abnormal DNA base repeats. For example, in myotonic dystrophy, a GCT triplet excess is currently the most sensitive test for that disease. The tests can be used for intrauterine diagnosis and prediction of whether the triplet is within the normal or mutant range. Thus, in many cases, the greater the number of repeats, the more severely involved the fetus or patient.

Muscle biopsy results. All are unreliable for diagnostic purposes.

Genetic testing is increasingly available for common disorders, such as Duchenne and spinal muscle atrophy, as well as less common disorders found in Table 23–25.

Therapy for Duchenne muscular dystrophy continues to be frustrating. Prednisone in low doses has increased muscle strength and prolonged ambulation. Research emphasis is on gene therapy, but there is great difficulty in finding viral vectors able to carry the very large dystrophin gene into muscle cells.

Sumner C: Therapeutics development for spinal muscular atrophy. NeuroRx 2006;3:235 [PMID: 16554261].

BENIGN ACUTE CHILDHOOD MYOSITIS

Benign acute childhood myositis (myalgia cruris epidemica) is characterized by transient severe muscle pain and weakness affecting mainly the calves and occurring 1–2 days following an upper respiratory tract infection. Although symptoms involve mainly the gastrocnemius muscles, all skeletal muscles appear to be invaded directly by virus; recurrent episodes are due to different viral types. By seroconversion or isolation of the virus, acute myositis has been shown to be largely due to influenza types B and A and occasionally due to parainfluenza and adenovirus.

MYASTHENIA GRAVIS

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Weakness, chiefly of muscles innervated by the brainstem, usually coming on or increasing with use (fatigue).
- Positive response to neostigmine and edrophonium.
- Acetylcholine receptor antibodies in serum (except in congenital form).

**General Considerations**

Myasthenia gravis is characterized by easy fatigability of muscles, particularly the extraocular muscles and those of mastication, swallowing, and respiration. In the neonatal period, however, or in early infancy, the weakness may be so constant and general that an affected infant may present nonspecifically as a “floppy infant.” Girls are affected more frequently than boys. The age at onset is older than 10 years in 75% of patients, often shortly after menarche. If diagnosed before age 10 years, congenital myasthenia should be considered in retrospect. Thyrotoxicosis is found in almost 10% of affected female patients. The essential abnormality is a circulating antibody that binds to the acetylcholine receptor protein and thus reduces the number of motor end plates for binding by acetylcholine.

**Clinical Findings**

**A. Symptoms and Signs**

1. **Neonatal (transient) myasthenia gravis**—This disorder occurs in 12–19% of infants born to myasthenic mothers. The condition is due to maternal acetylcholine receptor antibody transferred across the placenta; a thymic factor in the infant may also be involved. Maternal thymectomy may reduce the transfer rate.

ASA, acetylsalicylic acid; CK, creatine kinase; CPT, carnitine palmityl transferase; CSF, cerebrospinal fluid; CT, computed tomography; ECG, electrocardiogram; EMG, electromyogram; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; SIDS, sudden infant death syndrome.

Gravis is not caused by receptor antibodies and often responds poorly to therapy. It may result from a genetic abnormality of the acetylcholine receptor protein, postsynaptic membrane structure, or other myoneural transmission defects.
more prominent signs are difficulty in chewing, dysphagia, a nasal voice, ptosis, and ophthalmoplegia. Pathologic fatigability of limbs, chiefly involving the proximal limb and neck muscles, may be more prominent than the bulbar signs and may lead to an initial diagnosis of conversion hysteria, muscular dystrophy, or polymyositis. Weakness may be limited to ocular muscles only. Associated disorders include autoimmune conditions, especially thyroid disease.

An acute fulminant form of myasthenia gravis has been reported in children aged 2–10 years, who present with rapidly progressive respiratory difficulties. Bulbar paralysis may evolve within 24 hours. The differential diagnosis includes Guillain-Barré syndrome and bulbar poliomyelitis. Administration of anticholinesterase agents establishes the diagnosis and is lifesaving. Rarely, myasthenia can be postinfectious, and slowly resolve to normal.

B. Laboratory Findings

1. Neostigmine test—In newborns and very young infants, the neostigmine test may be preferable to the edrophonium (Tensilon) test because the longer duration of its response permits better observation, especially of sucking and swallowing movements. There is a delay of about 10 minutes before the effect may be manifest. The physician should be prepared to suction secretions, and administer atropine if necessary.

2. Edrophonium test—Testing with edrophonium is used in older children who are capable of cooperating in certain tasks, such as raising and lowering their eyelids and squeezing a sphygmomanometer bulb or the examiner’s hands. Ophthalmologic tests of ocular motility with edrophonium are often positive in patients able to cooperate. Maximum improvement occurs within 2 minutes.

3. Other laboratory tests—Serum acetylcholine receptor antibodies or muscle-specific receptor tyrosine kinase (MuSK) are often found in the neonatal and juvenile forms. In juveniles, thyroid studies are appropriate.

C. Electrical Studies of Muscle

Repetitive stimulation of a motor nerve at slow rates (3/s) with recording over the appropriate muscle reveals a progressive fall in amplitude of the muscle potential in myasthenic patients. A maximal stimulus must be given. At higher rates of stimulation (50/s), there may be a transient repair of this defect before the progressive decline is seen. If this study is negative, single-fiber EMG may be helpful diagnostically.

D. Imaging

Chest radiograph and CT scanning in older children may disclose benign thymus enlargement. Thymus tumors are rare in children.

 Treatment

A. General and Supportive Measures

In the newborn or in a child in myasthenic or cholinergic crisis (see item 5 in the following section), suctioning of secretions is essential. Respiratory assistance may be required. Treatment should be conducted by physicians with experience in this disorder.

B. Anticholinesterase Drug Therapy

1. Pyridostigmine bromide—The dosage must be adjusted for each patient. A frequent starting oral dosage is 15–30 mg orally every 6 hours, or 1 mg/kg per dose every 6 hours in pediatric patients.

2. Neostigmine—Fifteen milligrams of neostigmine are roughly equivalent to 60 mg of pyridostigmine bromide. Neostigmine often causes gastric hypermotility with diarrhea, but it is the drug of choice in newborns, in whom prompt treatment may be lifesaving. It may be given parenterally.

3. Atropine—Atropine may be added on a maintenance basis to control mild cholinergic side effects such as hypersecretion, abdominal cramps, and nausea and vomiting.

4. Immunologic intervention—Such intervention is achieved primarily with prednisone and recently with mycophenolate mofetil. Plasmapheresis is effective in removing acetylcholine receptor antibody in severely affected patients. More potent immunomodulators, such as azathioprine, are occasionally necessary.

5. Myasthenic crisis—Relatively sudden difficulties in swallowing and respiration may be observed in myasthenic patients. Edrophonium results in dramatic but brief improvement; this may make evaluation of the condition of the small child difficult. Suctioning, tracheostomy, respiratory assistance, and fluid and electrolyte maintenance may be required.

6. Cholinergic crisis—Cholinergic crisis may result from overdosage of anticholinesterase drugs. The resulting weakness may be similar to that of myasthenia, and the muscarinic effects (diarrhea, sweating, lacrimation, miosis, bradycardia, and hypotension) are often absent or difficult to evaluate. The edrophonium test may help to determine whether the patient is receiving too little of the drug or is manifesting toxic symptoms due to overdosage. Improvement after the drugs are withdrawn suggests cholinergic crisis. A respirator should be available. The patient may require atropine and tracheostomy.

C. Surgical Measures

Early video thoracoscopic thymectomy is beneficial in many patients whose disease is not confined to ocular symptoms; the effects may be delayed. Experienced surgical and postsurgical
cases; in others, the side of the face affected may have abutted consecutive live births. Forceps delivery is the cause in some

PERIPHERAL NERVE PALSY

1. Facial Weakness

Facial asymmetry may be present at birth or may develop later, either suddenly or gradually, unilaterally or bilaterally. Nuclear or peripheral involvement of the facial nerves results in sagging or drooping of the mouth and inability to close one or both eyes, particularly when newborns and infants cry. Inability to wrinkle the forehead may be demonstrated in infants and young children by getting them to follow a light moved vertically above the forehead. Loss of taste of the anterior two thirds of the tongue on the involved side may be demonstrated in cooperative children by age 4 or 5 years. Playing with a younger child and the judicious use of a tongue blade may enable the physician to note whether the child’s face puckers up when something sour (eg, lemon juice) is applied with a swab to the anterior tongue. Ability to wrinkle the forehead is preserved, owing to bilateral innervation, in supranuclear facial paralysis.

Injuries to the facial nerve at birth occur in 0.25–6.5% of consecutive live births. Forceps delivery is the cause in some cases; in others, the side of the face affected may have abutted in utero against the sacral prominence. Often, no cause can be established.

Acquired peripheral facial weakness (Bell palsy) of sudden onset and unknown cause is common in children. It often follows a viral illness (postinfectious) or physical trauma (eg, cold). It may be a presenting sign of Lyme disease, infectious mononucleosis, herpes simplex, or Guillain-Barré syndrome and is usually diagnosable by the history, physical examination, and appropriate laboratory tests. Chronic cranial nerve VII palsy may be a sign of brainstem tumor.

Bilateral facial weakness in early life may be due to agenesis of the facial nerve nuclei or muscles (part of Möbius syndrome) or may even be familial. Myasthenia gravis, polynuclear paralysis (Miller-Fisher syndrome), and myotonic dystrophy or other congenital myopathies must be considered.

Asymmetrical crying facies, in which one side of the lower lip depresses with crying (this is the normal side) and the other does not, is usually an innocent form of autosomal dominant inherited congenital malformation. The defect in the parent (the asymmetry often improves with age) may be almost inapparent. EMG suggests congenital absence of the depressor angularis muscle of the lower lip. Forceps pressure is often erroneously incriminated as a cause of this innocent congenital anomaly. Occasionally other major (eg, cardiac septal defects) congenital defects accompany the palsy. Authorities vary in the incidence of major anomalies (10%) and extent of investigations; testing for chromosome 22q11 deletion, careful cardiac evaluation, and assessment of serum calcium level may be pertinent.

In the vast majority of cases of isolated peripheral facial palsy—both those due to birth trauma and those acquired later—improvement begins within 1–2 weeks, and near or total recovery of function is observed within 2 months. In severe palsy with inefficient blinking, methylcellulose drops, 1%, should be instilled into the eyes to protect the cornea during the day; at night the lid should be taped down with cellophane tape. Upward massage of the face for 5–10 minutes three or four times a day may help maintain muscle tone. Prednisone therapy (2–4 mg/kg orally for 5–7 days) likely does not aid recovery. In the older child, acyclovir or valacyclovir (herpes antiviral agent) therapy or antibiotics (Lyme disease) may have a role in Bell palsy.

In the few children with permanent and cosmetically disfiguring facial weakness, plastic surgical intervention at age 6 years or older may be of benefit. New procedures, such as attachment of facial muscles to the temporal muscle and transplantation of cranial nerve XI, are being developed.

CHAPTER 23

Polyneuropathy is usually insidious in onset and slowly progressive. Children present with disturbances of gait and easy fatigability in walking or running, and slightly less often, weakness or clumsiness of the hands. Pain, tenderness, or paresthesias are mentioned less frequently. Neurologic examination discloses muscular weakness, greatest in the distal portions of the extremities, with steppage gait and depressed or absent deep tendon reflexes. Cranial nerves are sometimes affected. Sensory deficits occur in a stocking-and-glove distribution. The muscles may be tender, and trophic changes such as glassy or parchment skin and absent sweating may occur. Rarely, thickening of the ulnar and peroneal nerves may be felt. In sensory neuropathy the patient may not feel minor trauma or burns, and thus allows trauma to occur.

Known causes include (1) toxins (lead, arsenic, mercurials, vincristine, and benzene); (2) systemic disorders (diabetes mellitus, chronic uremia, recurrent hypoglycemia, porphyria, polyarteritis nodosa, and lupus erythematosus); (3) inflammatory states (chronic or recurrent Guillain-Barré syndrome and neuritis associated with mumps or diphtheria); (4) hereditary, often degenerative conditions, which in some classifications include certain storage diseases, leukodystrophies, spinocerebellar degenerations with neurogenic components, and Bassen-Kornzweig syndrome; and (5) hereditary sensory or combined motor and sensory neuropathies. Polyneuropathies associated with malignancies, vitamin deficiencies, or excessive vitamin B<sub>6</sub> intake are not reported or are exceedingly rare in children.

The most common chronic motor neuropathy of insidious onset often has no identifiable cause. This chronic inflammatory demyelinating neuropathy (CIDP) is assumed to be immunologically mediated and may have a relapsing course. Sometimes facial weakness occurs. CSF protein levels are elevated. Nerve conduction is slowed, and findings on nerve biopsy are abnormal. Immunologic abnormalities are seldom demonstrated, although nerve biopsy findings may show round cell infiltration. Corticosteroids, repeated IVIG, and, occasionally, immunosuppressants may give long-term benefit.

Clinical Findings

Hereditary neuropathy is the most common documented cause of chronic neuropathy in childhood. A careful genetic history (pedigree) and examination and electrical testing (motor and sensory nerve conduction and EMG) of patient and relatives are keys to diagnosis. Genetic tests are available for many of the variants. Nerve biopsy is rarely necessary.

Other hereditary neuropathies may have ataxia as a prominent finding, often overshadowing the neuropathy. Examples are Friedreich ataxia, dominant cerebellar ataxia, and Marinsesco-Sjögren syndrome. Finally, some hereditary neuropathies are associated with identifiable and occasionally treatable metabolic errors (see Tables 23–20 and 23–21). These disorders are described in more detail in Chapter 34.

Laboratory diagnosis of chronic polyneuropathy is made by measurement of motor and sensory nerve conduction velocities. EMG may show a neurogenic polyphasic pattern. CSF protein levels are often elevated, sometimes with an increased IgG index. Nerve biopsy, with teasing of the fibers and staining for metachromasia, may demonstrate loss of myelin, and to a lesser degree, loss of axons and increased connective tissue or concentric lamellas (so-called onion-skin appearance) around the nerve fiber. Muscle biopsy may show the pattern associated with denervation. Other laboratory studies directed toward specific causes mentioned above include screening for heavy metals and for metabolic, renal, or vascular disorders.

Treatment & Prognosis

Therapy is directed at specific disorders whenever possible. Corticosteroid therapy is used first when the cause is unknown or neuropathy is considered to be due to chronic inflammation (this is not the case in acute Guillain-Barré syndrome [AIDP; acute inflammatory demyelinating neuropathy]). Prednisone is initiated at 2–4 mg/kg/d orally, with tapering to the lowest effective dose; it may need be reinstituted when symptoms recur. (Prednisone should probably not be used for treatment of hereditary neuropathy.) Immunosuppressants and, occasionally, immunosuppressants may give long-term benefit.
IVIG, plasmapheresis, mycophenolate mofetil, and rituximab are choices.

The long-term prognosis varies with the cause and the ability to offer specific therapy. In the corticosteroid-dependent group, residual deficits are more frequent.

1. Paralytic Group

The hypotonic infant who is weak (appearing paralyzed) usually has a lesion of the lower motor neuron complex (Table 23–26). The child has significant lack of movement against gravity (e.g., fails to kick the legs, hold up the arms, or attempt to stand when held) or in response to stimuli such as tickling or slight pain. Infantile progressive spinal muscular atrophy (Werdnig-Hoffman disease) is the most common cause. Neuropathy is rare, Botulism and myasthenia gravis (rare) are neuromuscular junction causes. Myotonic dystrophy and rare myopathies (e.g., central core myopathy) are muscle disease entities.

In anterior horn cell or muscle disease, weakness is proximal (i.e., in shoulders and hips); fine motor movement is preserved. Tendon reflexes are absent or depressed; strength (to noxious stimuli) is decreased (paralytic). Intelligence is preserved. Fine motor, language, and personal and social milestones are normal, as measured, for example, on a Denver Developmental Screening Test (DDST, or Denver II) (see Chapter 2).

A. Myopathies

The congenital, relatively nonprogressive myopathies, muscular dystrophy, myotonic dystrophy, polymyositis, and periodic paralysis were discussed earlier in this chapter. Most cases of congenital or early infantile muscular dystrophy reported in the past probably represented congenital myopathies (see Table 23–25). Congenital muscular dystrophy, diagnosed by muscle biopsy, occurs in two forms: (1) a benign form, with gradual improvement in strength; and (2) a severe form, in which either weakness progresses rapidly and death occurs in the first months or year of life or severe disability is present with little or no progression but lifelong marked limitation of activity.

B. Glycogenosis with Muscle Involvement

Glycogen storage diseases are described in Chapter 34. Patients with type II disease (Pompe disease, due to a deficiency of acid maltase) are most likely to present as floppy infants. Muscle cramps on exertion or easy fatigabil-
ity, rather than floppiness in infancy, is the presenting complaint in type V disease (McArdle phosphorylase deficiency) or in the glycogenosis due to phosphofructokinase deficiency or phosphohexose isomerase inhibition.

### C. Myasthenia Gravis

Neonatal transient and congenital persistent myasthenia gravis, with patients presenting as paralytic floppy infants, is described earlier in this chapter.

### D. Arthrogryposis Multiplex (Congenital Deformities About Multiple Joints)

This symptom complex, sometimes associated with hypotonia, may be of neurogenic or myopathic origin (or both) and may be associated with a variety of other anomalies. Orthopedic aspects are discussed in Chapter 24.

### E. Spinal Cord Lesions

Severe limpness in newborns following breech extraction with stretching or actual tearing of the lower cervical to upper thoracic spinal cord is rarely seen today, owing to improved obstetric delivery. Klumpke lower brachial plexus paralysis may be present; the abdomen is usually exceedingly soft, and the lower extremities are flaccid. Urinary retention is present initially; later, the bladder may function autonomously. MRI of the cervical cord should define the lesion. After a few weeks, spasticity of the lower limbs becomes obvious. Treatment is symptomatic and consists of bladder and skin care and eventual mobilization on crutches or in a wheelchair.

### 2. Nonparalytic Group

The nonparalytic hypotonic infant often has a damaged brain (Table 23–27). Rarely, tendon reflexes may be depressed or

---
absent; usually, brisk reflexes (with hypotonia) point to “supra-
segmental” or cerebral dysfunction. Intrauterine or perinatal
insults to brain or upper cord, while sometimes difficult to
document, are major causes. (Occasionally, severe congenital
myopathies presenting in the newborn period simulate nonpar-
alytic hypotonia.) Persisting severe hypotonia is ominous. Tone
will often vary. Spasticity and other forms of cerebral palsy may
emerge; hypertonia and hypotonia may occur at varying times
or sites in the same infant. Associated choreoathetoid or ataxic
movements and developmental delay can clarify the diagnosis.
Tendon reflexes are usually increased; pathologic infant reflexes
(Babinski and tonic neck) may persist or worsen.

The creatine kinase level and the EMG are usually nor-
mal. Prolonged nerve conduction velocities (rare in this
situation) point to polyneuritis or leukodystrophy. Muscle
biopsy evaluation, using special stains and histographic anal-
ysis, often shows a reduction in size of type II fibers associ-
ated with decreased voluntary motor activity.

Limpness in the neonatal period and early infancy and
subsequent delay in achieving motor milestones are the
presenting features in a large number of children with a
variety of CNS disorders, including mental retardation, as in
trisomy 21. In many such cases, no specific diagnosis can be
made. Close observation and scoring of motor patterns and
adaptive behavior, as by the DDST, are helpful.

*See elsewhere in text for manifestations.
CNS, central nervous system.
The term cerebral palsy is a nonspecific term used to describe a chronic, static impairment of muscle tone, strength, coordination, or movements. The term implies that the condition is nonprogressive and originated from some type of cerebral insult or injury before birth, during delivery, or in the perinatal period. Other neurologic deficits or disorders (eg, blindness, deafness, or epilepsy) often coexist. Some form of cerebral palsy occurs in about 0.2% of neonatal survivors. The fundamental course, severity, precise manifestations, and prognosis vary widely.

The most common forms of cerebral palsy (75% of cases) involve spasticity of the limbs. A variety of terms denote the specific limb or combination of limbs affected: monoplegia (one limb); hemiplegia (arm and leg on same side of body, but arm more affected than leg); paraplegia (both legs affected with arms unaffected); quadriplegia (all four limbs affected equally).

Ataxia is the second most common form of cerebral palsy, accounting for about 15% of cases. The ataxia frequently affects fine coordinated movements of the upper extremities, but may also involve lower extremities and trunk. An involuntary movement disorder usually in the form of choreoathetosis accounts for 5% of cases and persistent hypotonia without spasticity for 1%.

Depending on the type and severity of the motor deficits, associated neurologic deficits or disorders may occur: seizures in up to 50%, mild mental retardation in 26%, and severe retardation in up to 27%. Disorders of language, speech, vision, hearing, and sensory perception are found in varying degrees and combinations.

The findings on physical examination are variable and are predominantly those of spasticity, hyperreflexia, ataxia, and involuntary movements. Microcephaly is frequently present. In patients with hemiplegia, the affected arm and leg may be smaller and shorter than the unaffected limbs. Cataracts, retinopathy, and congenital heart defects may be indicative of congenital infections such as CMV and rubella.

Appropriate laboratory studies depend on the history and physical findings. MRI scans may be helpful in understanding the full extent of cerebral injury, and occasionally neuroimaging results suggest specific etiologies (eg, periventricular calcifications in congenital CMV infections). Other diagnostic tests that may be considered include genetic studies based on history or MRI findings; urine amino acids and organic acids; and blood amino acids, lactate, pyruvate, and ammonia concentrations.

The determination that a child has cerebral palsy is based in part on excluding other neurologic disorders and following the child for a sufficient amount of time to ascertain the usually static, nonprogressive nature of the disorder.

Treatment and management are directed at assisting the child to attain maximal physical functioning and potential physical, occupational, and speech therapy; orthopedic monitoring and intervention and special educational assistance may all contribute to an improved outcome. Medications and injections (eg, botulinum toxin) for spasticity and seizures are needed in many children. A new treatment, constraint-induced (CI) movement therapy is being studied in controlled trials. Also important is the general support of the parents and family with counseling, educational programs, and support groups.

The prognosis for patients with cerebral palsy depends greatly on the child’s IQ, severity of the motor deficits, and degree of incapacity. Aspiration, pneumonia, or other intercurrent infections are the most common causes of death.

In contrast, patients with mild cerebral palsy may improve with age. Some patients experience resolution of their motor deficits by age 7 years. Many children with normal intellect have normal life spans and are able to lead productive, satisfying lives.

The cause is often obscure or multifactorial. No definite etiologic diagnosis is possible in 25% of cases. The incidence is high among infants small for gestational age. Intrauterine hypoxia is a frequent cause. Other known causes are intrauterine bleeding, infections, toxins, congenital malformations, obstetric complications (including birth hypoxia), neonatal infections, kernicterus, neonatal hypoglycemia, metabolic disorders, and a small number of genetic syndromes.

Orthopedics is the medical discipline that deals with disorders of the neuromuscular and skeletal systems. The most common complaints in orthopedics are pain, loss of function, and deformity. Although the medical history reveals the patient’s expectations, the physical examination and radiographic imaging are the most important tools of orthopedic diagnosis.

**DISTURBANCES OF PRENATAL ORIGIN**

**CONGENITAL AMPUTATIONS & LIMB DEFICIENCIES**

**General Considerations**

Congenital amputations are caused by teratogens (eg, drugs or viruses), amniotic bands, or metabolic diseases (eg, diabetes in the mother). Children with congenital limb deficiencies, such as absence of the femur, tibia, or fibula, also have a high incidence of associated congenital anomalies, including genitourinary and cardiac defects and cleft palate. A limb deficiency usually consists of partial absence of structures in the extremity along one side or the other. The effect on structures distal to the amputation varies. For example, in radial club hand, the entire radius is absent, while the thumb may be hypoplastic or absent. Longitudinal bone deficiency is almost always associated with complex tissue defects in the extremity because of abnormalities of the associated nerves and muscles.

**Treatment**

Mild limb deficiencies can be treated with limb lengthening or contralateral limb shortening, or both. More severe deficiencies are treated with prostheses to compensate for the length discrepancy. For some severe anomalies, surgery to remove a portion of the malformed extremity (eg, foot) is indicated so that a prosthesis can be fitted early.

Lower extremity prostheses are best fitted between ages 12 and 15 months, when walking starts. They are consistently well accepted, because they are necessary for balance and walking. In unilateral upper extremity amputation, fitting the child with a dummy-type prosthesis as early as age 6 months is advantageous because the child becomes accustomed to an extremity of the proper length and to the habit of bimanual manipulation. Children quickly learn how to function with a prosthesis and can lead active lives, even participating in sports. Although myoelectric prostheses have a technologic appeal, most patients find that simpler constructs are more useful in the long run.

**DEFORMITIES OF THE EXTREMITIES**

1. **Metatarsus Varus**

Metatarsus varus is a common congenital foot deformity characterized by inward deviation of the forefoot. A vertical crease in the arch is present in rigid deformities. The angulation is located at the base of the fifth metatarsal, and this bone is prominent. Most flexible deformities are secondary to intrauterine positioning pressure and usually resolve spontaneously. Ten to 15% of children with metatarsus varus also have hip dysplasia. A careful hip examination is mandatory. If the deformity is rigid and cannot be manipulated past the midline, it is worthwhile to use a cast changed at intervals of 2 weeks to correct the deformity. So-called corrective shoes do not live up to their name, although they can be used to maintain correction obtained by casting.

2. Clubfoot (Talipes Equinovarus)

The diagnosis of classic talipes equinovarus, or clubfoot, requires three features: (1) plantarflexion of the foot at the ankle joint (equinus), (2) inversion deformity of the heel (varus), and (3) medial deviation of the forefoot (varus). The incidence of clubfoot is approximately 1:1000 live births. There are three major categories of clubfoot: (1) idiopathic, (2) neurogenic, and (3) those associated with syndromes such as arthrogryposis and Larsen syndrome. Any infant with a clubfoot should be examined carefully for associated anomalies, especially of the spine. Idiopathic clubfeet may be hereditary.

▶ Treatment

Treatment consists of manipulation of the foot to stretch the contracted tissues on the medial and posterior aspects, followed by splinting to hold the correction. When treatment is instituted shortly after birth, correction is rapid. When treatment is delayed, the foot tends to become more rigid within a matter of days. After full correction is obtained, a night brace is necessary for long-term maintenance of correction. Treatment by casting requires patience and experience, but fewer patients require surgery when attention is paid to details of the Ponsetti technique. If the foot is rigid and resistant to casting, surgical correction by tendon release is appropriate. Fifteen to 50% of patients require surgical correction.

3. Developmental Dysplasia of the Hip Joint

The definition of dysplasia is abnormal growth or development. Dysplasia of the hip encompasses a spectrum of conditions in which there is an abnormal relationship between the proximal femur and the acetabulum. In the most severe condition, the femoral head is not in contact with the acetabulum and is classified as a dislocated hip. A dislocatable hip is one in which the femoral head lies within the acetabulum at rest but can be dislocated with a provocative maneuver. A subluxatable hip is one in which the femoral head comes partially out of the joint with a provocative maneuver. Acetabular dysplasia is a term describing insufficient acetabular development on radiograph.

Congenital dislocation of the hip occurs in approximately 1 in 1000 live births. At birth, both the acetabulum and femur are underdeveloped. Dysplasia becomes worse with growth unless the dislocation is corrected. If the dislocation is corrected in the first few days or weeks of life, the dysplasia is completely reversible and a normal hip will develop. In older children with persistent dislocation or subluxation, especially those who have begun walking, dysplasia will worsen to the point that it is irreversible. For this reason, it is important to recognize the deformity early.

▶ Clinical Findings

A. Newborn Infant

The diagnosis of hip dislocation in the newborn depends on demonstrating instability of the joint. The infant is placed supine and complete relaxation is obtained by feeding with a bottle if necessary. The examiner’s long finger is then placed over the greater trochanter and the thumb over the inner side of the thigh. Both hips are flexed 90 degrees and then slowly abducted from the midline, one hip at a time. With gentle pressure, an attempt is made to lift the greater trochanter forward. A feeling of slipping as the head relocates is a sign of instability (Ortolani sign). When the joint is more stable, the deformity must be provoked by applying slight pressure with the thumb on the medial side of the thigh as the thigh is adducted, thus slipping the hip posteriorly and eliciting a jerk as the hip dislocates (Barlow sign). The signs of instability are more reliable than a radiograph for diagnosing developmental dislocation of the hip in the newborn. Ultrasonography can be used but tends to result in overdiagnosis in the newborn. Asymmetrical skinfolds are present in about 40% of newborns and therefore are not particularly helpful.

B. Infants Aged 1–12 Months

After the first month of life, the signs of instability become less evident. Contractures begin to develop about the hip joint, limiting abduction to less than 90 degrees. It is important to hold the pelvis level to detect asymmetry of abduction. If the knees are at unequal heights when the hips and knees are flexed, the dislocated hip is on the side with the lower knee. If abduction is incomplete on examination, radiographs of the hips are indicated. After 6 weeks of age, radiologic examination is more accurate. Lateral displacement of the femoral head is the most reliable sign. In mild cases, the only radiologic abnormality may be an increased steepness of acetabular alignment and an acetabular angle greater than 35 degrees.

C. Children Older Than 1 Year

If dysplasia of the hip has not been diagnosed during the first year of life and the child begins to walk, there will be a painless limp and a lurch to the affected side. When the child stands on the affected leg, a dip of the pelvis will be evident on the opposite side, owing to weakness of the gluteus medius muscle. This is the Trendelenburg sign and accounts for the unusual swaying gait of children with unilateral hip dislocation. In children with bilateral dislocation, the loss of abduction is almost symmetrical and the findings may not be obvious. As a child with bilateral dislocation of the hips begins to walk, the gait is waddling. The perineum is widened as a...
result of lateral displacement of the hips, and there is flexion contracture as a result of posterior displacement of the femoral head. Flexion contracture contributes to a marked lumbar lordosis, and the greater trochanters are easily palpable in their elevated position. Treatment is still possible in the first 2 years of life, but the results are not nearly as good as in children receiving treatment early.

### Treatment

Dislocation or dysplasia diagnosed in the first few weeks or months of life can be treated by Pavlik harness, which maintains reduction by placing the hip in a flexed and abducted position. Forced abduction is contraindicated, because this can lead to avascular necrosis of the femoral head. The use of double or triple diapers is ineffective. An experienced pediatric orthopedic surgeon should supervise treatment of children requiring splints.

In the first 4 months of life, reduction can be obtained by flexing and abducting the hip; no other manipulation is usually necessary. In late cases, preoperative traction for 2–3 weeks relaxes the soft tissues about the hip and draws the femoral head down so it is opposite the acetabulum. Reduction can then be achieved without force under general anesthesia. After reduction, a hip spica cast is used for 6 months. After closed reduction, if the hip is not stable with a hip spica cast, open reduction is indicated. If the deformity is left untreated, a striking facial asymmetry will persist.

Acute torticollis may follow upper respiratory infection or mild trauma. Rotatory subluxation of the upper cervical spine requires computed tomography for accurate imaging. Traction or a cervical collar usually results in resolution of the symptoms within 1–2 days. Other causes of torticollis include spinal cord or cerebellar tumors, syringomyelia, and rheumatoid arthritis.

**GENERALIZED DISORDERS OF SKELETAL OR MESODERMAL TISSUES**

#### 1. Arthrogryposis Multiplex Congenita (Amyoplasia Congenita)

### Clinical Findings

Arthrogryposis multiplex congenita is characterized by incomplete fibrous ankylosis (usually bilateral) of many or all joints of the body. Upper extremity contractures usually produce adduction of the shoulders; extension of the elbows; flexion of the wrists; and stiff, straight fingers with poor muscle control of the thumbs. In the lower extremities, common deformities are dislocation of the hips, extension contractures of the knees, and severe clubfeet. The joints are fusiform and the joint capsules decreased in volume due to lack of movement during fetal development. Various investigations have attributed the basic defect to an abnormality of muscle or the lower motor neurons. Muscle development is poor, and muscles may be represented only by fibrous bands.

### Treatment

Passive mobilization of joints is the early treatment. Prolonged casting to correct deformities is contraindicated because it causes further stiffness. Removable splints combined with vigorous physical therapy are the most effective conservative treatments. Surgical release of the affected joints is often necessary. The clubfoot associated with arthrogryposis is very stiff and nearly always requires surgery. Surgery, including capsulotomy, osteotomy, and tendon lengthening, is used to correct deformities of the knees. In the young child, a dislocated hip may be reduced operatively by the medial approach. Multiple operative procedures on the hip joint are contraindicated because worsening stiffness and impaired of range of motion may be produced. Affected children are often able to walk if the dislocations and contractures are reduced surgically. The long-term prognosis for physical and vocational independence is guarded. These patients have normal intelligence.

**References**

2. Marfan Syndrome
Marfan syndrome is a connective tissue disorder characterized by unusually long fingers and toes (arachnodactyly); hypermobility of the joints; flatfeet; subluxation of the ocular lenses; other eye abnormalities, including cataract, coloboma, megalocornea, strabismus, and nystagmus; a high-arched palate; a strong tendency to scoliosis; pectus carinatum; and thoracic aortic aneurysms due to weakness of the media of the vessels (see Chapter 35). Serum mucoproteins may be decreased, and urinary excretion of hydroxyproline increased. The condition is easily confused with homocystinuria, because the phenotypic presentation is identical. The two diseases are differentiated by detecting homocystine in the urine of patients with homocystinuria.

Treatment of flatfeet is usually supportive. Scoliosis may require more vigorous treatment by bracing or spine fusion. The long-term prognosis has improved for patients because better treatment for their aortic aneurysms has been devised.

3. Klippel-Feil Syndrome
In Klippel-Feil syndrome some or all of the cervical vertebrae fail to separate. Multiple congenital spinal anomalies may be present, with hemivertebrae and scoliosis. The neck is short and stiff, the hairline is low, and the ears are low-set. Common associated defects include congenital scoliosis, cervical rib, spina bifida, torticollis, web neck, high scapula, renal anomalies, and deafness. If there is evidence of abnormal renal function, renal ultrasound is indicated as well as a hearing test. Scoliotic deformities, if progressive, are an indication for spinal arthrodesis.

4. Sprengel Deformity
Sprengel deformity is a congenital condition in which one or both scapulas are elevated and small. The child cannot raise the arm completely on the affected side, and torticollis may be present. The deformity occurs alone or in association with Klippel-Feil syndrome. If the deformity is functionally limiting, the scapula may be surgically relocated lower in the thorax. Excision of the upper portion of the scapula improves cosmetic appearance but has little effect on function.

5. Osteogenesis Imperfecta
Osteogenesis imperfecta is a rare genetic connective tissue disease characterized by multiple and recurrent fractures. The severe fetal type (osteogenesis imperfecta congenita) is characterized by multiple intrauterine or perinatal fractures. Moderately affected children have numerous fractures and are dwarved as a result of bony deformities and growth retardation. Intelligence is not affected. The shafts of the long bones are reduced in cortical thickness, and wormian bones are present in the skull. Other features include blue scleras, thin skin, hyperextensibility of ligaments, otosclerosis with hearing loss, and hypoplastic and deformed teeth. In the tarda type, fractures begin to occur at variable times after the perinatal period. There are relatively fewer fractures and deformities in these children. Affected patients are sometimes suspected of having suffered abuse. Osteogenesis imperfecta tarda should be ruled out in any case of nonaccidental trauma with multiple fractures.

Molecular genetic studies have identified more than 150 mutations of the COL1A1 and COL1A2 genes, which encode for type I procollagen. Parents without this mutation can be counseled that the likelihood of a second affected child is negligible.

Bisphosphonates show promise for decreasing the incidence of fractures. Surgical treatment involves correction of deformity of the long bones. Multiple intramedullary rods have been used to prevent deformity from fracture malunion. Patients are often confined to wheelchairs during adulthood.

6. Osteopetrosis (Osteitis Condensans Generalisata, Marble Bone Disease, Albers-Schönberg Disease)
Osteopetrosis is a rare disorder of osteoclastic resorption of bone, resulting in abnormally dense bones. The marrow spaces are reduced, resulting in anemia. There are two types: a milder autosomal dominant type and a more malignant autosomal recessive type. The findings may appear at any age. On radiologic examination, the bones show increased density, transverse bands in the shafts, clubbing of ends, and vertical striations of long bones. Thickening about the cranial foramina is present, and heterotopic calcification of soft tissues is possible.

The autosomal recessive form of osteopetrosis can be treated successfully by allogeneic bone marrow transplantation.

7. Achondroplasia (Classic Chondrodystrophy)
Achondroplasia is the most common form of short-limbed dwarism. The upper arms and thighs are proportionately shorter than the forearms and legs. Findings include bowing
of the extremities, a waddling gait, limitation of motion of major joints, relaxation of the ligaments, short stubby fingers of almost equal length, frontal bossing, moderate hydrocephalus, depressed nasal bridge, and lumbar lordosis. Intelligence and sexual function are normal. The disorder is transmitted in an autosomal dominant manner, but 80% of cases result from new mutations of the fibroblast growth factor receptor-3 (FGFR3) gene. Radiographs demonstrate short, thick tubular bones and irregular epiphysial plates. The ends of the bones are thick, with broadening and cupping. Epiphysial ossification may be delayed. Because the spinal canal is narrowed, a herniated disk in adulthood may lead to acute paraplegia. Growth hormone is given to some children with bone dysplasia. Limb lengthening surgery has been successful in alleviating some of the symptoms. Bone marrow transplantation will resolve as the primary problem is treated. Secondary curvature in which the convexity is to the right, which is the most common type of idiopathic curve. A mild degree of posterior curvature of the spine (kyphosis) is normal in the thoracic area. Excessive curvature is pathologic. Mild anterior curvature of the spine (lordosis) is normal in the lumbar and cervical spines. Idiopathic scoliosis generally begins at age 8 or 10 years and usually progresses during growth. In rare instances, infantile scoliosis may be seen in children aged 2 years or younger.

Idiopathic scoliosis is four to five times more common in girls than boys. Eighty percent of cases of scoliosis are idiopathic. Because 30% of family members are also affected, siblings of an affected child should be examined. The disorder is usually asymptomatic in adolescence, but severe curvature can cause pain or loss of pulmonary function in later years. The screening examination for scoliosis is performed by having the patient bend forward 90 degrees with the hands joined in the midline. Asymmetry of the height of the ribs or paravertebral muscles on one side indicates the rotation of the trunk associated with lateral curvature.

Diseases associated with scoliosis include neurofibromatosis, Marfan syndrome, cerebral palsy, muscular dystrophy, poliomyelitis, and myelodysplasia. Between 5% and 7% of cases of scoliosis are due to congenital vertebral anomalies such as a hemivertebra or unilateral vertebral bridge. These curves are more rigid than the common idiopathic curve (see later discussion) and often increase with growth, especially during adolescence.

Idiopathic infantile scoliosis, occurring in children age 2–4 years, is uncommon in the United States but more common in Great Britain. If the rib-vertebral angle of Mehta is less than 20 degrees, the curve will resolve spontaneously. If the angle is greater, the curve will progress. Sciatic scoliosis may result from pressure on the spinal cord or roots by infectious processes or herniation of the nucleus pulposus; the underlying cause must be sought. Secondary curvature will resolve as the primary problem is treated.

**Clinical Findings**

**A. Symptoms and Signs**

Scoliosis in adolescents does not cause significant pain. If a patient has significant pain, seek the underlying cause because the scoliosis is usually secondary to another disorder such as bone or spinal cord tumor. Deformity of the rib cage and asymmetry of the waistline are evident with curvatures of 30 degrees or more. Less severe curvature may be detected by the forward bending test described earlier. This test is designed to detect early abnormalities of rotation that may not be apparent when the patient is standing erect.

**B. Imaging**

The most valuable radiographs are those taken of the entire spine in the standing position in both the anteroposterior and lateral planes. Usually one primary curvature is evident with a compensatory curvature that develops to balance the
body. At times two primary curvatures may be seen, usually in the right thoracic and left lumbar regions. Any left thoracic curvature should be suspected of being secondary to neurologic disease and should prompt a more meticulous neurologic examination. If the curvatures of the spine are balanced (compensated), the head is centered over the center of the pelvis and the patient is “in balance.” If the spinal alignment is uncompensated, the head will be displaced to one side, which produces an unsightly deformity. Rotation of the spine may be measured by scoliometer. Rotation is associated with a marked rib hump as the lateral curvature increases in severity. Deformity of the rib cage causes long-term problems when lung volumes are reduced.

► Treatment

Treatment of scoliosis depends on curve magnitude, skeletal maturity, and risk of progression. Curvatures less than 20 degrees usually do not require treatment unless they show progression. Bracing is controversial but often used for curvatures of 20–40 degrees in a skeletally immature child. Treatment is indicated for any curvature that demonstrates progression on serial radiologic examination. Curvatures greater than 40 degrees are resistant to treatment by bracing. Thoracic curvatures greater than 60 degrees have been correlated with poor pulmonary function in adult life. Curvatures of such severity are an indication for surgical correction and posterior spinal fusion to maintain the correction. Curvatures of 40–60 degrees may also require spinal fusion if they are progressive, are causing decompensation of the spine, or cause unacceptable deformity.

Surgical fusion involves decortication of the bone over the laminas and spinous processes, with the addition of bone graft. Rods, hooks, or pedicle screws maintain postoperative correction, with activity restriction for several months until the bone fusion is solid. Treatment requires a team approach and is best done in centers with full support facilities.

► Prognosis

Compensated small curves that do not progress may be well tolerated throughout life, with minor deformity. Counsel the parents regarding the genetic transmission of scoliosis and caution that their children’s backs should be examined as part of routine physical examinations. Early detection allows for simple brace treatment. Severe scoliosis may require correction by spinal arthrodesis, although fusionless techniques are being developed.

----

SLIPPED CAPITAL FEMORAL EPIPHYSIS

Slipped capital femoral epiphysis (SCFE) is caused by displacement of the proximal femoral epiphysis due to disrup-

----

ORTHOPEDICS

Genu varum (bowleg) is normal from infancy through age 2 years. The alignment then changes to genu valgum (knock-knee) until about age 8 years, at which time adult alignment is attained. Criteria for referral to an orthopedist include persistent bowing beyond age 2 years, bowing that is increasing rather than decreasing, bowing of one leg only, and knock-knee associated with short stature.

Bracing may be appropriate. Rarely, an osteotomy is necessary for a severe problem such as Blount disease (proximal tibial epiphyseal dysplasia).

TIBIAL TORSION

“Toeing in” in small children is a common parental concern. Tibial torsion is rotation of the leg between the knee and the ankle. Internal rotation amounts to about 20 degrees at birth but decreases to neutral rotation by age 16 months. The deformity is sometimes accentuated by laxity of the knee ligaments, allowing excessive internal rotation of the leg in small children. In children who have a persistent internal rotation of the tibia beyond age 16–18 months, the condition is often due to sleeping with feet turned in and can be reversed with an external rotation splint worn only at night.

FEMORAL ANTEVERSION

Toeing in beyond age 2 or 3 years is usually secondary to femoral anteversion, which is characterized by more internal rotation of the hip compared with external rotation. This femoral alignment follows a natural history of progressive decrease toward neutral during growth. Studies comparing the results of treatment with shoes or braces to the natural history have shown that little is gained by active treatment. Active external rotation exercises, such as skating or bicycle riding, can be encouraged. Osteotomy for rotational correction is rarely required. Children who have no external rotation of hip in extension are candidates for orthopedic consultation.

COMMON FOOT PROBLEMS

When a child begins to stand and walk, the long arch of the foot is flat with a medial bulge over the inner border of the foot. The forefeet are mildly pronated or rotated inward, with a slight valgus alignment of the knees. As the child grows and joint laxity decreases, the long arch is better supported and more normal relationships occur in the lower extremities. (See also sections on Metatarsus Varus and Clubfoot, earlier.)

1. Flatfoot

Flatfoot is a normal condition in infants. If the heel cord is of normal length, full dorsiflexion is possible with the heel in the neutral position. As long as the heel cord is of normal length and a longitudinal arch is noted when the child is sitting in a non-weight-bearing position, the parents can be assured that a normal arch will probably develop. There is usually a familial incidence of relaxed flatfeet in children who have no apparent arch. In any child with a shortened heel cord or stiffness of the foot, other causes of flatfoot such as tarsal coalition or vertical talus should be ruled out by a complete orthopedic examination and radiograph.

In the child with an ordinary relaxed flatfoot, no active treatment is indicated unless calf or leg pain is present. In children who have leg pains attributable to flatfoot, a supportive shoe with scaphoid pad, such as a good-quality sports shoe, is useful. An orthotic that holds the heel in neutral and supports the arch may relieve discomfort if more support is needed. An arch insert should not be prescribed unless passive correction of the arch is easily accomplished; otherwise, the skin over the medial side of the foot will be irritated.

2. Talipes Calcaneovalgus

Talipes calcaneovalgus is characterized by excessive dorsiflexion at the ankle and eversion of the foot. It is often present at birth and is due to intrauterine position. Treatment consists of passive exercises, stretching the foot into plantarflexion. In rare instances, it may be necessary to use plaster casts to help with manipulation and positioning. Complete correction is the rule.

3. Cavus Foot

This deformity consists of an unusually high longitudinal arch of the foot. It may be hereditary or associated with neurologic conditions such as poliomyelitis, Charcot-Marie-Tooth disease, Friedreich ataxia, and diastematomyelia. There is usually an associated contracture of the toe extensor, producing a claw toe deformity in which the metatarsophalangeal joints are hyperextended and the interphalangeal joints acutely flexed. Any child presenting with cavus feet should receive a careful neurologic examination and radiographs of the spine.

Conservative therapy is ineffective. In symptomatic cases, surgery may be necessary to lengthen the contracted extensor and flexor tendons and to release the plantar fascia and other tight plantar structures. The associated varus heel deformity causes more problems than the high arch.

4. Bunions (Hallux Valgus)

Adolescents may present with lateral deviation of the great toe associated with a prominence over the head of the first metatarsal. This deformity is painful only with shoe wear and almost always can be relieved by fitting shoes that are wide enough in the toe. Surgery should be avoided in the adolescent, because further growth tends to cause recurrence of the deformity.

DEGENERATIVE PROBLEMS (ARTHRITIS, BURSITIS, & TENOSYNOVITIS)

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Chronic condition.
- May result from overuse in adolescent athletes.
- Rule out more serious conditions first.

Degenerative arthritis may follow childhood skeletal problems, such as infection, slipped capital femoral epiphysis, avascular necrosis, or trauma, or it may occur in association with hemophilia. Early effective treatment of these disorders can prevent arthritis. Degenerative changes in the soft tissues around joints may occur as a result of overuse syndrome in adolescent athletes. Young boys throwing excessive numbers of pitches, especially curve balls, may develop "Little League" elbow, consisting of degenerative changes around the humeral condyles associated with pain, swelling, and limitation of motion (see Chapter 25). Limitation of the number of pitches thrown by Little League pitchers is the key to prevention.

Acute bursitis is uncommon in childhood, and other causes should be ruled out before this diagnosis is accepted.

Tenosynovitis is most common in the region of the knees and feet. Children taking dancing lessons, particularly toe dancing, may have pain around the flexor tendon sheaths in the toes or ankles. Rest is effective treatment. At the knee level, the patellar ligament may be irritated, with associated swelling in the infrapatellar fat pad. Synovitis in this area is usually due to overuse and is treated by rest and nonsteroidal anti-inflammatory drugs. Corticosteroid injections are contraindicated.

TRAUMA

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Directed physical examination shows swelling, tenderness, deformity, or instability.
- Radiographic findings are consistent with forceful injury.
- Rule out physeal fracture.

**SOFT TISSUE TRAUMA (SPRAINS, STRAINS, & CONTUSIONS)**

A sprain is the stretching of a ligament. A strain is a stretch of a muscle or tendon. Contusions are generally due to tissue compression, with damage to blood vessels within the tissue and the formation of hematoma. A severe sprain is one in which the ligament is completely disrupted, resulting in instability of the joint. In a mild or moderate sprain, tearing of the ligament is incomplete, but local pain and swelling results. Mild or moderate sprain is not associated with instability of the joint.

The initial treatment of mild or moderate sprain consists of ice, compression, and elevation. Brief splinting followed by early range of motion of the affected joint protects against further injury and relieves swelling and pain. Ibuprofen and other nonsteroidal anti-inflammatory drugs are useful for pain.

In more severe trauma with tearing of a ligament, instability of the joint may be demonstrated by gross examination or by stress testing with radiographic documentation. Such deformity of the joint may cause persistent instability resulting from inaccurate apposition of the ligament ends during healing. If instability is evident, surgical repair of the torn ligament may be indicated. If a muscle is torn at its tendinous insertion, it should be repaired.

1. **Ankle Sprains**

The history will indicate that the injury was by either forceful inversion or eversion. The more common inversion injury results in tearing or injury to the lateral ligaments, whereas an eversion injury will injure the medial ligaments of the ankle. The injured ligaments may be identified by means of careful palpation for point tenderness around the ankle. The joint should be supported or immobilized at a right angle, which is the functional position. Use of an air splint produces joint rest, and the extremity can be protected by using crutches. Functional rehabilitation, including edema control, range-of-motion exercises, strengthening, and restitution of proprioceptive sensation, can prevent long-term disability.

2. **Knee Sprains**

Sprains of the collateral and cruciate ligaments are uncommon in children. These ligaments are so strong that it is more common to injure the growth plates, which are the weakest structures in the knees of children. In adolescence, however, the physes have started to close, and the knee joint is more like that of an adult. Rupture of the anterior cruciate ligament can result from a rotational injury (see Chapter 25). If the injury produces avulsion of the tibial spine, anatomic reduction and fixation is often required.

Effusion of the knee after trauma should be referred to an orthopedic specialist. The differential diagnosis includes torn ligament, torn meniscus, and osteochondral fracture. Nontraumatic effusion should be evaluated for inflammatory conditions (eg, juvenile rheumatoid arthritis) or patellar malalignment.
3. Internal Derangements of the Knee

Meniscal injuries are uncommon in children younger than age 12 years. Clicking or locking of the knee may occur in young children as a result of a discoid lateral meniscus, a rare congenital anomaly. As the child approaches adolescence, internal damage to the knee from a torsion weight-bearing injury may cause tearing and displacement of a meniscus and result in locking of the knee. Osteochondral fractures secondary to osteochondritis dissecans may also present as internal derangements of the knee in adolescence. Post-traumatic synovitis may mimic a meniscal lesion. In any severe injury to the knee, epiphysial injury should be suspected. Stress films will sometimes demonstrate separation of the distal femoral epiphysis in such cases. Epiphysial injury should be suspected whenever tenderness is present on both sides of the metaphysis of the femur after injury.

Disability is great, with local swelling and heat and extreme pain on the slightest motion of the adjacent joint. The limb should be rested until the local reaction has subsided (5–7 days). After local heat and tenderness have decreased, gentle active exercises may be initiated. Passive stretching exercises are not indicated, because they may stimulate the ossification reaction. If surgery is necessary, it should not be attempted before 9 months to 1 year after injury, because it may restart the process and lead to an even more severe reaction.

5. Contusions

Contusion of muscle with hematoma formation produces the familiar “charley horse” injury. Treatment of such injuries is by application of ice, compression, and rest. Exercise should be avoided for 5–7 days. Local heat may hasten healing once the acute phase of tenderness and swelling is past.

6. Myositis Ossificans

Ossification within muscle occurs when there is sufficient trauma to cause a hematoma that later heals in the manner of a fracture. The injury is usually a contusion and occurs most commonly in the quadriceps of the thigh or the triceps of the arm. When a severe injury with hematoma is recognized, it is important to splint the extremity and avoid activity. If further trauma causes recurrent injury, ossification may reach spectacular proportions and resemble an osteosarcoma.
knee. Radiologic examination confirms the diagnosis. The patella may be reduced by extending the knee and placing slight pressure on the patella while gentle traction is exerted on the leg. In subluxation of the patella, the symptoms may be more subtle, and the patient will complain that the knee “gives out” or “jumps out of place.”

In patients with first-time dislocation, the initial treatment should be nonoperative, consisting of physical therapy to strengthen the quadriceps, hips, and core stabilizers. Surgery is reserved for individuals with reparable osteochondral injuries, loose bodies, and recurrent dislocation following appropriate nonoperative therapy.

FRACTURES

1. Epiphysial Separations

In children, epiphysial separations and fractures are more common than ligamentous injuries. This finding is based on the fact that the ligaments of the joints are generally stronger than the associated growth plates. In instances in which dislocation is suspected, a radiograph should be taken to rule out epiphysial fracture. Radiographs of the opposite extremity, especially for injuries around the elbow, may be valuable for comparison. Reduction of a fractured epiphysis should be done under anesthesia to align the growth plate with the least amount of force. Fractures across the growth plate may produce bony bridges that will cause premature cessation of growth or angular deformities of the extremity. Epiphysial fractures around the shoulder, wrist, and fingers can usually be treated by closed reduction, but fractures of the epiphyses around the elbow often require open reduction. In the lower extremity, accurate reduction of the epiphyseal plate is necessary to prevent joint deformity if a joint surface is involved. If angular deformities result, corrective osteotomy may be necessary.

2. Torus Fractures

Torus fractures consist of “buckling” of the cortex due to compression of the bone. They usually occur in the distal radius or ulna. Alignment is usually satisfactory, and simple immobilization for 3 weeks is sufficient.

3. Greenstick Fractures

Greenstick fractures involve frank disruption of the cortex on one side of the bone but no discernible cleavage plane on the opposite side. These fractures are angulated but not displaced, because the bone ends are not separated. Reduction is achieved by straightening the arm into normal alignment, and reduction is maintained by a snugly fitting plaster cast. Follow-up radiographs should be obtained after 7–10 days to ensure that the reduction has been maintained in the cast. A slight angular deformity can be corrected by remodeling of the bone. The farther the fracture is from the growing end of the bone, the longer the time required for remodeling. The fracture can be considered healed when no tenderness or local heat is present and when adequate bony callus is seen on radiograph.

4. Fracture of the Clavicle

Clavicular fractures are very common injuries in infants and children. The arm can be immobilized in a sling for comfort. The healing callus will be apparent when the fracture has consolidated, but this unsightly lump will generally resolve over a period of months to a year. (See also Chapter 25.)

5. Supracondylar Fractures of the Humerus

Supracondylar fractures tend to occur in children aged 3–6 years and are potentially dangerous because of the proximity to the brachial artery in the distal arm. As they are usually associated with significant trauma, swelling may be severe. Most often, these fractures are treated by closed reduction and percutaneous pinning. Complications associated with supracondylar fractures include Volkmann ischemic contracture of the forearm due to vascular compromise and cubitus varus (decreased carrying angle) secondary to poor reduction. The so-called gunstock deformity of the elbow may be somewhat unsightly but does not usually interfere with joint function.

6. General Comments on Other Fractures in Children

Reduction of fractures in children is usually accomplished by simple traction and manipulation; open reduction is indicated if a satisfactory alignment is not obtained. Remodeling of the fracture callus usually produces an almost normal appearance of the bone over a matter of months. The younger the child, the more remodeling is possible. Angular deformities remodel reliably. Rotatory malalignment does not remodel.

The physician should be suspicious of child abuse whenever the age of a fracture does not match the history given or when the severity of the injury is more than the alleged accident would have produced. In suspected cases of battering in which no fracture is present on the initial radiograph, a repeat radiograph 10 days later is in order. Bleeding beneath the periosteum will be calcified by 7–10 days, and the radiographic appearance is almost diagnostic of severe closed trauma characteristic of a battered child.
Osteomyelitis is an infectious process that usually starts in the spongy or medullary bone and then extends to involve compact or cortical bone. The lower extremities are most often affected, and there is commonly a history of trauma. Osteomyelitis may occur as a result of direct bacterial invasion through a penetrating wound or open fracture, but hematogenous spread of infection (eg, pyoderma or upper respiratory tract infection) from other infected areas is much more common. The most common infecting organism is Staphylococcus aureus, which has a tendency to infect the metaphyses of growing bones. Anatomically, circulation in the long bones is such that the blood supply to the metaphysis just below the growth plate is provided by end arteries, which turn sharply to the end in venous sinusoids, causing a relative stasis. In the infant younger than age 1 year, there is direct vascular communication with the epiphysis across the growth plate, so that direct spread may occur from the metaphysis to the epiphysis and subsequently into the joint. In the older child, the growth plate provides an effective barrier, the epiphysis is usually not involved. In the older child, infection spreads retrograde from the metaphysis into the diaphysis, and by rupture through the cortical bone and along the diaphysis beneath the periosteum.

1. Exogenous Osteomyelitis
To avoid osteomyelitis by direct extension, all wounds must be carefully cleansed. Osteomyelitis is a common occurrence from pressure sores in anesthetic areas, as in patients with spina bifida. Cultures of the wound at the time of exploration and debridement may be useful if signs of infection develop subsequently. Copious irrigation is necessary, and all nonviable skin, subcutaneous tissue, fascia, and muscle must be excised. In extensive or contaminated wounds, antibiotic coverage is indicated. Contaminated lacerations should be left open and secondary closure performed 3–5 days later. At the time of delayed closure, any remaining necrotic tissue should be excised. Leaving the wound open allows the infection to stay at the surface rather than extend inward to the bone. Puncture wounds are especially liable to cause osteomyelitis and should be carefully debrided.

Initially, broad-spectrum antibiotics should be administered, but the final choice of antibiotics is directed by culture results. A tetanus toxoid booster may be indicated. Gas gangrene is best prevented by adequate debridement. After exogenous osteomyelitis has become established, treatment becomes more complicated, requiring extensive surgical debridement and intravenous antibiotics.

2. Hematogenous Osteomyelitis
Hematogenous osteomyelitis is usually caused by pyogenic bacteria; 85% of cases are due to staphylococci. Streptococci are a less common cause of osteomyelitis. Pseudomonas organisms are common in cases of nail puncture wounds. Children with sickle cell anemia are especially prone to osteomyelitis caused by Salmonella spp.

- Clinical Findings
  A. Symptoms and Signs
In infants, the manifestations of osteomyelitis may be subtle, presenting as irritability, diarrhea, or failure to feed properly; the temperature may be normal or slightly low; and the white blood cell count may be normal or only slightly elevated. There may be pseudoparalysis of the involved limb. In older children, the manifestations are more striking, with local tenderness and pain, high fever, rapid pulse, and elevated white blood cell count, erythrocyte sedimentation rate (ESR), and C-reactive protein. Osteomyelitis of a lower extremity often occurs around the knee joint in children aged 7–10 years. Tenderness is most marked over the metaphysis of the bone where the process originates. Lower extremity osteomyelitis should be ruled out in any child who refuses to bear weight.

  B. Laboratory Findings
Blood cultures are often positive early. The most significant test in infancy is the aspiration of pus. It is useful to needle the bone in the area of suspected infection and aspirate any fluid present. This fluid should be stained for organisms and cultured. Even edema fluid may be useful for determining the causative organism. Elevation of the ESR above 50 mm/h is typical for osteomyelitis. C-reactive protein is elevated earlier than the ESR.

  C. Imaging
Nonspecific local swelling is the first radiographic finding, followed by elevation of the periosteum. Formation of new bone from the cambium layer of the periosteum occurs after 3–6 days. As the infection becomes chronic, areas of cortical bone are isolated by pus spreading down the medullary canal, causing rarefaction and demineralization of the bone. Such isolated pieces of cortex become ischemic and form sequestra (dead bone fragments). These radiographic findings are late but specific. Osteomyelitis should be diagnosed clinically before significant radiographic findings are present. Bone scan is sensitive but nonspecific and should be interpreted in the clinical context before radiographic findings become positive. Magnetic resonance imaging can demonstrate edema early or soft-tissue thickening later.

- Treatment
  A. Specific Measures
Antibiotics should be started intravenously as soon as the diagnosis of osteomyelitis is made. Oral antibiotics are begun
PYOGENIC ARTHRITIS

The source of pyogenic arthritis varies with age. In the infant, pyogenic arthritis often develops by spread from adjacent osteomyelitis. In the older child, it presents as an isolated infection, usually without bony involvement. In teenagers with pyogenic arthritis, an underlying systemic disease or infection with an organism (eg, gonococcus) that has an affinity for joints is usually the cause.

The infecting organism also varies with age: group B streptococcus and *S. aureus* in those younger than age 4 months; *Haemophilus influenzae* and *S. aureus* in those aged 4 months to 4 years; and *S. aureus* and *S. pyogenes* in older children and adolescents. *H. influenzae* is now uncommon because of effective immunization. *Kingella kingae* is a gram-negative bacterium that occasionally causes pyarthrosis.

**Clinical Findings**

**A. Symptoms and Signs**

In older children, the signs may be striking, with fever, malaise, vomiting, and restriction of motion. In infants, paralysis of the limb due to inflammatory neuritis may be evident. Infection of the hip joint in infants should be suspected if decreased abduction of the hip is present in an infant who is irritable or feeding poorly. A history of umbilical catheter treatment in the newborn nursery should alert the physician to the possibility of pyogenic arthritis of the hip.

**B. Laboratory Findings**

The initial effusion of the joint rapidly becomes purulent. An effusion of the joint may accompany osteomyelitis in the adjacent bone. A white cell count exceeding 50,000/μL in the joint fluid indicates a definite purulent infection. Generally, spread of infection is from the bone into the joint, but unattended pyogenic arthritis may also affect adjacent bone. The ESR is often above 50 mm/h.

**C. Imaging**

Early distention of the joint capsule is nonspecific and difficult to measure on radiograph. In the infant with unrecognized pyogenic arthritis, dislocation of the joint may follow within a few days as a result of distention of the capsule by pus. Later changes include destruction of the joint space, resorption of epiphysial cartilage, and erosion of the adjacent bone of the metaphysis. The bone scan shows increased flow and increased uptake about the joint.

**Treatment**

Aspiration of the joint is the key to diagnosis. In the hip joint, pyogenic arthritis is most easily treated by surgical drainage because the joint is deep, difficult to aspirate, and inaccessible to thorough cleaning by needle aspiration. Arthroscopic irrigation and debridement have been successful in treating pyogenic arthritis of the knee. If fever and clinical symptoms do not subside within 24 hours after initial treatment, open surgical drainage is indicated. Antibiotics can be selected based on the child’s age, results of the Gram stain, and culture of the aspirated pus. Reasonable empiric therapy for infants is nafcillin or oxacillin plus a third-generation cephalosporin. An antistaphylococcal agent alone is usually adequate for children older than age 5 years.
For staphylococcal infections, 3 weeks of therapy is recommended; for other organisms, 2 weeks is usually sufficient. Oral therapy may be begun when clinical signs have improved markedly. It is not necessary to give intra-articular antibiotics, because good levels are achieved in the synovial fluid with parenteral administration.

**Prognosis**

The prognosis for the patient with pyogenic arthritis is excellent if the joint is drained early, before damage to the articular cartilage has occurred. If infection is present for more than 24 hours, dissolution of the proteoglycans in the articular cartilage takes place, with subsequent arthrosis and fibrosis of the joint. Damage to the growth plate may also occur, especially within the hip joint, where the epiphyseal plate is intracapsular.

Widespread use of radiographs for the detection of joint involvement may have contributed to the increased recognition of transient synovitis of the hip. The condition is not usually associated with laboratory abnormalities. Toxemia is rare, and the white blood cell count is normal or only slightly elevated. Elevation of the erythrocyte sedimentation rate is rarely associated with elevation of the ESR, white blood cell count, or temperature above 38.3°C. It usually affects children aged 3–10 years and is more common in boys than girls. Motion of the hip joint is limited, particularly internal rotation, and radiographic changes are nonspecific, with some swelling apparent in the soft tissues around the joint.

Treatment consists of bed rest and mild traction with slight flexion of the hip. Nonsteroidal anti-inflammatory drugs shorten the course of the disease, although even with no treatment, the disease usually runs its course in days. Follow-up radiographs of the hip are important because toxic synovitis may be the precursor of avascular necrosis of the femoral head in a small percentage of patients. Radiographs can be obtained at 6 weeks, or earlier if either a persistent limp or pain is present.

**TUBERCULOUS ARTHRITIS**

Tuberculous arthritis is now a rare disease in the United States, but children in poor social circumstances are at risk for the infection. Generally tuberculous arthritis may be ruled out by negative skin testing. The joints most commonly affected in children are the intervertebral disks, resulting in gibbus or dorsal angular deformity at the site of involvement. Treatment is by local drainage of the abscess, followed by antituberculous therapy. Prolonged immobilization in a plaster cast or prolonged bed rest is necessary to promote healing. Spinal fusion may be required to preserve stability of the vertebral column.

**DISKITIS**

Diskitis is pyogenic infectious spondylitis in children; supportive treatment and intravenous antibiotics are likely to lead to rapid relief of symptoms and signs without recurrence.

**TRANSIENT SYNOVITIS OF THE HIP**

The most common cause of limping and pain in the hip in children in the United States is transitory synovitis, an acute inflammatory reaction that often follows an upper respiratory infection. It is generally self-limited. In questionable cases, aspiration of the hip joint yields only yellowish fluid with low protein and few if any neutrophils. Toxic synovitis of the hip is rarely associated with elevation of the ESR, white blood cell count, or temperature above 38.3°C. It usually affects children aged 3–10 years and is more common in boys than girls. Motion of the hip joint is limited, particularly internal rotation, and radiographic changes are nonspecific, with some swelling apparent in the soft tissues around the joint.

Treatment consists of bed rest and mild traction with slight flexion of the hip. Nonsteroidal anti-inflammatory drugs shorten the course of the disease, although even with no treatment, the disease usually runs its course in days. Follow-up radiographs of the hip are important because toxic synovitis may be the precursor of avascular necrosis of the femoral head in a small percentage of patients. Radiographs can be obtained at 6 weeks, or earlier if either a persistent limp or pain is present.

AVASCULAR NECROSIS OF THE PROXIMAL FEMUR (LEGG-CALVÉ-PERTHES DISEASE)

The vascular supply of the proximal femur is precarious, and when it is interrupted, necrosis results.

Clinical Findings

A. Symptoms and Signs

The highest incidence of Legg-Calvé-Perthes disease is between ages 4 and 8 years. Persistent pain is the most common symptom, and the patient may present with limp or limitation of motion.

B. Laboratory Findings

Laboratory findings, including studies of joint aspirates, are normal.

C. Imaging

Radiographic findings correlate with the progression of the process and the extent of necrosis. The early finding is effusion of the joint associated with slight widening of the joint space and periarticular swelling. Decreased bone density in and around the joint is apparent after a few weeks. The necrotic ossification center appears denser than the surrounding viable structures, and the femoral head is collapsed or narrowed.

As replacement of the necrotic ossification center occurs, rarefaction of the bone occurs in a patchwork fashion, producing alternating areas of rarefaction and relative density, referred to as “fragmentation” of the epiphysis.

In the hip, widening of the femoral head may occur associated with flattening, or coxa plana. If infarction has extended across the growth plate, a radiolucent lesion will be evident within the metaphysis. If the growth center of the femoral head has been damaged so that normal growth is arrested, shortening of the femoral neck results.

Eventually, complete replacement of the epiphysis develops as living bone replaces necrotic bone by creeping substitution. The final shape of the head depends on the extent of the necrosis and collapse of weakened bone.

Differential Diagnosis

Differential diagnosis includes inflammation, infection, and dysplasia. Transient synovitis of the hip may be distinguished from Legg-Calvé-Perthes disease by serial radiographs.

Treatment

The principle of treatment is protection of the joint. If the joint is deeply seated within the acetabulum and normal joint motion is maintained, a reasonably functional hip can result. Little benefit has been shown from bracing.

Prognosis

The prognosis for complete replacement of the necrotic femoral head in a child is excellent, but the functional result depends on the amount of deformity that develops during the time the softened structure exists. In Legg-Calvé-Perthes disease, the prognosis depends on the extent of involvement of the epiphysial center. In general, patients with metaphysial defects, those in whom the disease develops late in childhood, and those who have more complete involvement of the femoral head have a worse prognosis.

OSTEOCHONDRITIS DISSECANS

In osteochondritis dissecans, a wedge-shaped necrotic area of bone and cartilage develops adjacent to the articular surface. The fragment of bone may be broken off from the host bone and displaced into the joint as a loose body. If it remains attached, the necrotic fragment may be completely replaced by creeping substitution.

The pathologic process is the same as that described previously for avascular necrosing lesions of ossification centers. Because these lesions are adjacent to articular cartilage, however, joint damage may occur. The most common sites of these lesions are the knee (medial femoral condyle), the elbow joint (capitellum), and the talus (superior lateral dome). Joint pain is the usual presenting complaint. However, local swelling or locking may be present, particularly if a fragment is free in the joint. Laboratory studies are normal.

Treatment consists of protecting the involved area from mechanical damage. If a fragment is free-floating within the joint, it must be removed. For some marginal lesions, it may

be worthwhile to drill the necrotic fragment to encourage more rapid vascular ingrowth and replacement. If large areas
of a weight-bearing joint are involved, secondary degenerative
arthritis may result. Adolescents have less favorable
outcomes with nonoperative therapy.

Wall E, Von Stein D: Juvenile osteochondritis dissecans. Orthop

ORTHOPEDIC ASPECTS OF CEREBRAL PALSY

Early physical therapy to encourage completion of the nor-
mal developmental patterns may benefit patients with cere-
bral palsy. The greatest gains from this therapy are obtained
during the first few years of life, and therapy should not be
continued when no improvement is apparent.

Bracing and splinting are of questionable benefit,
although night splints may be useful in preventing equinus
deforrmity of the feet or adduction contractures of the hips.
Orthopedic surgery is useful for treating joint contractures
that interfere with function. In general, muscle transfers
are unpredictable in cerebral palsy, and most orthopedic pro-
ductures are directed at tendon lengthening or bony stabiliza-
tion by osteotomy or arthrodesis.

Flexion and adduction of the hip due to hyperactivity of
the adductors and flexors may produce a progressive para-
lytic dislocation of the hip, which can lead to pain and
dysfunction. Treatment of this dislocation is difficult and
unsatisfactory. The principal preventive measure is abduc-
tion bracing, but this must often be supplemented by release
of the adductors and hip flexors in order to prevent disloca-
tion. In severe cases, osteotomy of the femur may also be
necessary to correct the bony deformities of femoral antever-
sion and coxa valga that are invariably present. Patients with
a predominantly athetotic pattern are poor candidates for
any surgical procedure or bracing.

Because it is difficult to predict the outcome of surgical
procedures in cerebral palsy, the surgeon must examine
patients on several occasions before any operative procedure
is undertaken. Follow-up care by a physical therapist to
maximize the anticipated long-term gains should be
arranged before the operation.

15076595].

ORTHOPEDIC ASPECTS OF MYELODYSPLASIA

Patients born with spina bifida cystica (aperta) should be
examined early by an orthopedic surgeon. The level of
neurologic involvement determines the muscle imbalance
that will be present and apt to produce deformity with
growth. The involvement is often asymmetrical and tends to
change during the first 12–18 months of life. Early closure of
the sac is the rule, although there has been some hesitancy to
provide treatment to all of these patients because of the
extremely poor prognosis associated with congenital hydro-
cephalus, high levels of paralysis, and associated congenital
anomalies. A high percentage of these children have hydro-
cephalus, which may be evident at birth or shortly thereafter,
requiring shunting. Associated musculoskeletal problems
may include clubfoot, congenital dislocation of the hip,
arthrogryposis-type changes of the lower extremities, and
genital scoliosis. The most common lesions are at the
level of L3–4 and tend to affect the hip joint, with progressive
dislocation occurring during growth. Foot deformities may
be in any direction and are complicated by the fact that
sensation is generally absent. Spinal deformities develop in a
high percentage of these children, with scoliosis present in
approximately 40%. Ambulation may require long leg
braces. Careful urologic follow-up must be obtained to
prevent complications from bladder dysfunction.

In children who have a reasonable likelihood of walking,
operative treatment consists of reduction of the hip and
alignment of the feet in the weight-bearing position as well
as stabilization of the scoliosis. In children who lack active
quadriceps function and extensor power of the knee, the
likelihood of ambulation is greatly decreased. In such
patients, aggressive surgery in the hip region may result in
stiffening of the joints, thus preventing sitting. Multiple foot
operations are also contraindicated in these children.

The overall treatment of the child with spina bifida
should be coordinated in a multidisciplinary clinic where
various medical specialists work with therapists, social work-
ers, and teachers to provide the best possible care.

Mazur JM, Kyle S: Efficacy of bracing the lower limbs and
ambulation training in children with myelomeningocele. Dev

NEOPLASIA OF THE
MUSCULOSKELETAL SYSTEM

Neoplastic diseases of the musculoskeletal system are a
serious problem because of the poor prognosis of malignant
tumors arising in bone or other tissues derived from meso-
derm. Fortunately, few of the benign lesions undergo malig-
nant transformation. Accurate diagnosis depends on correla-
tion of the clinical, radiographic, and microscopic findings.
Complaints about the knee should be investigated for tumor,
although the usual causes of knee pain are traumatic, infec-
tious, or developmental in origin.

Lewis VO: Limb salvage in the skeletally immature patient. Curr
OSTEOCHONDROMA
Osteochondroma is the most common bone tumor in children. It usually presents as a pain-free mass. When present, pain is caused by adventitious bursitis or tendinitis due to irritation by the tumor. The lesion may be single or multiple. Pathologically, the lesion is a bone mass capped with cartilage. These masses tend to grow during childhood and adolescence in proportion to the child's growth.

On radiograph, the tumors tend to be in the metaphyseal region of long bones and may be pedunculated or sessile. The cortex of the underlying bone "flows" into the base of the tumor. An osteochondroma should be excised if it interferes with function, is frequently traumatized, or is large enough to be deforming. The prognosis is excellent. Malignant transformation is very rare.

OSTEID OSTEOMA
Osteoid osteoma classically produces night pain that can be relieved by nonsteroidal anti-inflammatory drugs. On physical examination there usually is tenderness over the lesion. An osteoid osteoma in the upper femur may cause pain referred to the knee.

On radiograph, the lesion is a radiolucent nidus surrounded by dense osteosclerosis that may obscure the nidus. Bone scan shows intense uptake in the lesion.

Surgical incision or radiofrequency ablation of the nidus is curative and may be done using computed tomography imaging and minimally invasive technique. The prognosis is excellent, with no known cases of malignant transformation, although the lesion has a tendency to recur.

ENCHONDROMA
Enhondroma is usually a silent lesion unless it produces a pathologic fracture. On radiograph it is radiolucent, usually in a long bone. A speckled calcification may be present. The classic lesion looks as though someone dragged his or her fingernails through clay, making streaks in the bones. Enchondroma is treated by surgical curettage and bone grafting. The prognosis is excellent. Malignant transformation may occur but is very rare in childhood.

CHONDROBLASTOMA
In chondroblastoma, the presenting complaint is pain around a joint. This neoplasm may produce a pathologic fracture. On radiograph, the lesion is radiolucent and usually located in the epiphysis. Calcification is unusual, with little or no reactive bone. The lesion is treated by surgical curettage and bone grafting. The prognosis is excellent if complete curettage is performed. There is no known malignant transformation.

NONOSSIFYING FIBROMA
Nonossifying fibroma is also called benign cortical defect and is nearly always an incidental finding on radiograph. The most frequent sites are the distal femur and proximal tibia. Nonossifying fibroma is a radiolucent lesion eccentrically located in the bone. Usually a thin sclerotic border is evident. Multiple lesions may be present. No treatment is needed because these lesions heal as they ossify with maturation of the bone and growth.

OSTEOSARCOMA
In osteosarcoma, the presenting complaint is usually pain in a long bone, although functional loss, the mass of the tumor, or limp may be the complaint. Pathologic fracture is common. The malignant osseous tumor produces a destructive expanding and invasive lesion. A triangle may be adjacent to the tumor produced by elevated periosteum and subsequent tumor ossification. The lesion may contain calcification and violates the cortex of the bone. Femur, tibia, humerus, and other long bones are the sites usually affected.

Surgical excision (limb salvage) or amputation is indicated based on the extent of the tumor. The lesion is radioresistant and does not respond to radiation therapy. Adjuvant chemotherapy is routinely used prior to surgical excision. The prognosis is improving, with 60–70% long-term survival rates being reported in modern series. Death usually occurs as a result of lung metastasis.

EWING SARCOMA
In Ewing sarcoma, the presenting complaint is usually pain and tenderness. Fever and leukocytosis may also be present, which makes osteomyelitis the main differential diagnosis. The lesion may be multicentric. Ewing sarcoma is radiolucent and destroys the cortex, frequently in the diaphyseal region. Reactive bone formation may occur about the lesion, seen as successive layers of so-called onion skin layering.

Treatment is with multiagent chemotherapy, radiation, and surgical resection. The prognosis is poor in patients with large tumor size, pelvic lesions, and poor response to chemotherapy.

MISCELLANEOUS DISEASES OF BONE

FIBROUS DYSPLASIA
Dysplastic fibrous tissue replacement of the medullary canal is accompanied by the formation of metaplastic bone in fibrous dysplasia. Three forms of the disease are recognized:
monostotic, polyostotic, and polyostotic with endocrine disturbances (precocious puberty in females, hyperthyroidism, and hyperadrenalism [Albright syndrome]).

Clinical Findings

A. Symptoms and Signs

The lesion or lesions may be asymptomatic. Pain, if present, is probably due to pathologic fractures. In females, endocrine disturbances may be present in the polyostotic variety and associated with café-au-lait spots.

B. Laboratory Findings

Laboratory findings are normal unless endocrine disturbances are present, in which case secretion of gonadotropic, thyroid, or adrenal hormones may be increased.

C. Imaging

The lesion begins centrally within the medullary canal, usually of a long bone, and expands slowly. Pathologic fracture may occur. If metaplastic bone predominates, the contents of the lesion will be of the density of bone. The disease is often asymmetrical, and limb length disturbances may occur as a result of stimulation of epiphysial cartilage growth. Marked deformity of the bone may result, and a shepherd’s crook deformity of the upper femur is a classic feature of the disease.

Differential Diagnosis

The differential diagnosis includes other fibrous lesions of bone as well as destructive lesions such as unicameral bone cyst, eosinophilic granuloma, aneurysmal bone cyst, nonossifying fibroma, enchondroma, and chondromyxoid fibroma.

Treatment & Prognosis

If the lesion is small and asymptomatic, no treatment is needed. If the lesion is large and produces or threatens pathologic fracture, curettage and bone grafting are indicated. Unless the lesions impair epiphysial growth, the prognosis for patients with fibrous dysplasia is good. Lesions tend to enlarge during the growth period but are stable during adult life. Malignant transformation is rare.

UNICAMERAL BONE CYST

Unicameral bone cyst occurs in the metaphysis of a long bone, usually in the femur or humerus. It begins within the medullary canal adjacent to the epiphysial cartilage. It probably results from some fault in enchondral ossification. The cyst is considered active as long as it abuts onto the metaphysial side of the epiphysial cartilage, and there is a risk of growth arrest with or without treatment.

When a border of normal bone exists between the cyst and the epiphysial cartilage, the cyst is inactive. The lesion is usually identified when a pathologic fracture occurs, producing pain. Laboratory findings are normal. On radiograph, the cyst is identified centrally within the medullary canal, producing expansion of the cortex and thinning over the widest portion of the cyst.

Treatment consists of curettage and bone grafting. The cyst may heal after a fracture.

ANEURYSMAL BONE CYST

Aneurysmal bone cyst is similar to unicameral bone cyst, but it contains blood rather than clear fluid. It usually occurs in a slightly eccentric position in the long bone, expanding the cortex of the bone but not breaking the cortex. Involvement of the flat bones of the pelvis is less common. On radiographs, the lesion appears somewhat larger than the width of the epiphysial cartilage. This feature distinguishes it from unicameral bone cyst.

Chromosomal abnormalities have been associated with aneurysmal bone cyst. The lesion may appear aggressive histologically, and it is important to differentiate it from osteosarcoma or hemangioma. Treatment is by curettage and bone grafting. The prognosis is good.

INFANTILE CORTICAL HYPEROSTOSIS (CAFFEY SYNDROME)

Infantile cortical hyperostosis is a benign disease of unknown cause that has its onset before age 6 months and is characterized by irritability, fever, and nonsuppurating, tender, painful swellings. Swellings may involve almost any bone of the body and are frequently widespread. Classically, swellings of the mandible and clavicle occur in 50% of patients; swellings of the ulna, humerus, and ribs also occur. The disease is limited to the shafts of bones and does not involve subcutaneous tissues or joints. It is self-limited but may persist for weeks or months. Anemia, leukocytosis, an increased ESR, and elevation of the serum alkaline phosphatase concentration are usually present. Cortical hyperostosis is demonstrable by a typical radiographic appearance and may be diagnosed on physical examination by an experienced pediatrician.

Fortunately the disease appears to be decreasing in frequency. Indomethacin may be useful for treatment. The prognosis is good, and the disease usually terminates without deformity.

GANGLION

A ganglion is a smooth, small cystic mass connected by a pedicle to the joint capsule, usually on the dorsum of the
wrist. It may also occur in the tendon sheath over the flexor surfaces of the fingers. These ganglia can be excised if they interfere with function or cause persistent pain.

**BAKER CYST**

A Baker cyst is a herniation of the synovium in the knee joint into the popliteal region. In children, the diagnosis may be made by aspiration of mucinous fluid, but the cyst nearly always disappears with time. Whereas Baker cysts may be indicative of intra-articular disease in the adult, they occur without internal derangement in children and rarely require excision.

Sports medicine as a separate discipline has grown since the 1980s in response to an expanding body of knowledge in the areas of exercise physiology, biomechanics, and musculoskeletal medicine. As more and more children participate in recreational and competitive activities, an understanding of sports medicine and developmental issues will be of major importance to pediatric health care providers.

### BASIC PRINCIPLES

The basic unit of the musculoskeletal system is the muscle fiber, which can be classified as slow twitch, fast twitch, or intermediate type. Slow twitch (type 1) fibers are usually smaller, are recruited in muscle contractions first, and are innervated by smaller motor neurons. Fast twitch (type 2) fibers make up white muscle and are usually larger. They are recruited when the body needs to produce rapid muscle tension. They produce more lactic acid than type 1 fibers. An intermediate (type 2a) fiber is called fast oxidative glycolytic, or FOG. Untrained individuals have a 50:50 proportion of type 1 to type 2 fibers. Elite long distance runners can have up to 90% type 1 fibers. This apparent adaptation raises a question as to whether an athlete is genetically programmed or can develop adaptations that allow success in sports.

Exercise generates cardiorespiratory system responses, including increased VO\textsubscript{2} max (maximum amount of oxygen that can be consumed), increased cardiac output, reduced resting heart rate, and improved blood pressure responses.

Biomechanics is the study of movement and how the forces generated by the neuromuscular system translate into movement. It integrates principles of both biology and physics. Through biomechanics we can understand the intricacies of movement and how these movements affect athletic performance and result in injuries.

### Types of Muscle Contraction Associated with Exercise

Muscle contractions are divided into three types: isometric, isotonic, and isokinetic. An isometric exercise is exercise against a fixed load in which no movement is achieved. Isometric exercise improves strength at a given angle, but does not affect endurance. Isometric exercise is beneficial for therapy during the acute phase of an injury in which certain muscles or groups of muscles need strengthening. Isometric exercise can cause an increase in blood pressure and heart rate and should be used cautiously if a cardiac condition is present.

Isokinetic exercise uses the concept of constant velocity and can provide maximal muscle contractions through full range of motion. This type of exercise generally requires special equipment. Lastly, isotonic exercise uses the principle of constant load and muscle length changes to strengthen muscles. It is the most common type of exercise and can be sport-specific. Isotonic exercises can be further classified as below:

#### A. Concentric Exercise

In concentric exercises, the force of muscle contraction overcomes an external resistance, which results in shortening of the muscle. These muscles accelerate a distal segment in the kinetic chain and are therefore referred to as open kinetic chain movements. An example of such an exercise is a biceps curl, during which the biceps is actively contracting or shortening to lift the weight.

#### B. Eccentric Exercise

In eccentric exercises, contractions increase muscle tension associated with lengthening of the muscle and are used to decelerate a distal segment in the kinetic chain. This type of exercise is exemplified by the squatting motion, in which the quadriceps lengths under tension to control downward motion. If the terminal segment in the chain is fixed, this type of movement is called closed kinetic chain movement.
Strength Training

Strength is defined as the peak force that can be generated during a single maximal contraction. Strength training uses progressive resistance to improve an athlete’s ability to resist or exert force. This can be achieved by a variety of techniques, including body weight, free weight, or machine resistance. The benefits of weight training are improved performance, endurance, and muscular strength. Weight training can be started in prepubescent athletes and if designed appropriately can be done safely with minimal risk of injury. Tanner staging (see Chapter 32) helps to define readiness for progression to more strenuous programs. Power lifting and weight lifting should be restricted to athletes who have reached or passed Tanner stage V. Individuals at Tanner stage IV or less can safely participate in a strength training program that is specifically and carefully designed for younger athletes. These programs incorporate submaximal resistance with multiple repetitions. They can be generalized or sport-specific. Care should be taken to prevent injuries while using weight-training equipment at home. Children and adults with disabilities can benefit from weight-training programs modified to meet their specific needs.

PREPARTICIPATION HISTORY & PHYSICAL EXAMINATION

The preparticipation medical examination evaluates and screens for potential medical problems that could occur during athletic participation. The objectives of this evaluation are to establish baseline medical information, detect any medical condition that might limit athletic participation, evaluate the athlete for preventable injuries, meet the legal or insurance requirements of most states, assess the athlete’s maturity, and make recommendations for protective equipment. The ideal timing of the examination is at least 4–6 weeks before training starts. This allows time for any needed interventions by the physician.

Preparticipation History

The history is the most important part of the encounter. Many key elements need to be explored with the athlete. Standardized history forms are available both on the Internet and in monographs. Figure 25–1A is one example of the essential questions contained in a preparticipation history. The history must include the following areas:

A. Cardiovascular History

The physician should note any history of cardiac murmurs, chest pain at rest or with exertion, syncopal episodes or sudden fatigue, shortness of breath, or recent illnesses with chest pain. The family history should specifically ask about underlying cardiac diseases, including hypertrophic cardiomyopathy, prolonged QT syndrome, Marfan syndrome, arrhythmias, and sudden death in family members. These questions may help identify potentially life-threatening cardiac lesions. The most common causes of sudden death in young athletes on the playing field are hypertrophic cardiomyopathy and congenital heart lesions.

B. History of Hypertension

Any history of hypertension requires investigation. The current guidelines for the diagnosis of hypertension are blood pressure above 130/75 mm Hg in a child younger than age 10 years or blood pressure above 140/85 mm Hg in a child 10 years of age or older.

C. History of Chronic Diseases

Diseases such as reactive airway disease or exercise-induced asthma, diabetes, renal disease, liver disease, chronic infections, neurologic disorders, or hematologic diseases should be noted.

D. Musculoskeletal Limitations and Prior Injuries

The physician should explore limited range of motion and muscle weakness along with prior injuries that may affect future performance. Chronic pain or soreness long after activity may reflect overuse syndromes that should be evaluated.

E. Menstrual History in Females

The physician should pay particular attention to the so-called female athletic triad: amenorrhea, eating disorders, and osteoporosis.

F. Nutritional Issues

The physician should record methods the athlete uses to maintain, gain, or lose weight.

G. Medication History

This information will provide data on current medications whose side effects may suggest activity modifications. Also, documenting drug use may provide the opportunity to explore with the patient drawbacks of using performance-enhancing compounds such as anabolic steroids, creatine, stimulants, and narcotics.

Cleared for sports: **YES or NO** If not cleared for sport **WHY?**

Further evaluation/rehab or/secondary clearance: ____________________________________________

Signature examinee: ___________________________ Date ____________________________

▲ Figure 25-1. B: Preparticipation examination.
Physical Examination

The physical examination should be focused on the needs of the athlete. It may be the only time that an athlete has contact with medical personnel and can be used to promote wellness along with screening for physical activity. Figure 25–1B is an example of a preparticipation physical exam form. The examination should include routine vital signs, including blood pressure measurements obtained in the upper extremity. The cardiovascular examination should include palpation of pulses, auscultation for murmurs in both sitting and standing, and evaluation of the effects of exercise on the individual. The musculoskeletal examination is used to determine strength, range of motion, flexibility, and previous injuries. Included is a quick guide that can be used to screen for abnormalities in this area (Table 25–1). The remainder of the examination should emphasize the following areas:

A. Skin
Are there any contagious lesions such as herpes or impetigo?

B. Vision
Are there any visual problems? Is there any evidence of retinal problems? Are both eyes intact?

C. Abdomen
Is there any evidence of hepatosplenomegaly?

D. Genitourinary System
Are any testicular abnormalities or hernias present?

E. Neurologic System
Are there any problems with coordination, gait, or mental processing?

F. Sexual Maturity
What is the individual’s Tanner stage?

Recommendations for Participation

After completing the medical evaluation the physician can make recommendations about sports clearance. The options are unrestricted participation, limited participation, or no

*If any abnormalities are found, a more focused evaluation is required.*
Participation in sports can have great benefits. It provides physical activity, acquisition of motor skills, and social opportunities. All sports participation, however, carries an inherent risk of injuries. These injuries are classified as either acute or chronic. Chronic injuries occur over time and are related to repetitive stress. These injuries develop in response to overuse, repeated microtrauma, and inadequate repair of injured tissue. Acute injuries or macrotrauma are one-time events that can cause alterations in biomechanics and physiology.

Response to an acute injury occurs in two predictable phases. The first week is characterized by an acute inflammatory response. During this time initial vasconstriction is followed by vasodilation. Chemical mediators of inflammation are released, resulting in the classical physical findings of local swelling, warmth, pain, and loss of function. This phase is essential in healing of the injury. The proliferative phase occurs over the next 2–4 weeks and involves repair and clean-up. Fibroblasts infiltrate and lay down new collagen. Lastly, the maturation phase allows for repair and regeneration of the damaged tissues.

The management of acute sports injuries is geared toward optimizing healing and restoring function. The goals of immediate care are to minimize the effects of the injury by reducing pain and swelling, to educate the athlete about the nature of the injury and how to take care of it, and to maintain the health of the rest of the body. The treatment for an acute injury is captured in the acronym PRICE:

- Protect the injury from further damage (taping, splints, braces)
- Rest the area
- Ice
- Compression of the injury
- Elevation immediately

Nonsteroidal anti-inflammatory drugs (NSAIDs) reduce the inflammatory response and reduce discomfort. These medications may be used immediately after the injury. Glucocorticoids should be administered judiciously. If administered inappropriately they may prolong the acute phase of recovery. Therapeutic use of physical modalities, including early cold and later heat, hydrotherapy, massage, electrical stimulation, iontophoresis, and ultrasound, can enhance recovery in the acute phase.

The recovery phase can be lengthy and requires athlete participation. Initial treatment is focused on joint range of motion and flexibility. Range-of-motion exercises should follow a logical progression of starting with passive motion, then moving to active assistive, and finally to active movement. Active range of motion is initiated once normal joint range has been reestablished. Flexibility exercises are sport-specific and aimed at reducing tight musculature. Strength training can begin early in this phase of rehabilitation. Initially only isometric exercises are encouraged. As recovery progresses and flexibility increases, isotonic and isokinetic exercises can be added to the program. These should be done at least three times per week.

</tbody>
</table>

(continuation)
As the athlete approaches near-normal strength and is pain-free, the final maintenance phase can be introduced. During this phase the athlete continues to build strength and work on endurance. The biomechanics of sport-specific activity need to be analyzed and retraining incorporated into the exercise program. Generalized cardiovascular conditioning should continue during the entire rehabilitation treatment.

### COMMON SPORTS MEDICINE ISSUES & INJURIES

#### INFECTIOUS DISEASES

Infectious diseases are common in both recreational and competitive athletes. These illnesses have an effect on basic physiologic function and athletic performance. Given this knowledge, physicians, parents, and coaches can adopt the common-sense guidelines listed in Table 25–3.

### HEAD & NECK INJURIES

Head and neck injuries occur most commonly in contact and individual sports. The sports with the highest incidences of brain injury are football, bicycling, baseball, horseback riding, and golf. The treatment of these injuries is controversial, and multiple guidelines have been developed. As a general rule, however, treatment of injuries in young children should be as conservative as possible because of their developing central nervous systems.

1. **Concussion**

Concussion is a temporary and immediate impairment of neurologic function and may or may not have an associated period of unconscious. It is usually defined by the duration of the loss of consciousness (LOC), post-traumatic

<table>

<tr>
<td>Athletes who have had recent infectious mononucleosis can return to noncontact training at 3 wk as long as there is no splenic enlargement. They may return to contact sports after 4 wk and a normal abdominal examination.</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Athletes with a streptococcal pharyngitis can resume activity once treatment has been initiated and they are afebrile. If a localized herpes gladiatorum or impetigo lesion is present, no contact sports are allowed until the lesions have resolved. Athletes with herpes zoster have the same restrictions. There are no restrictions for athletes with common warts. Athletes with molluscum contagiosum can compete if the affected areas are covered. Athletes with furuncles cannot be involved in contact sports or swimming until the lesions are healed. Athletes with HIV infection may compete in all types of sports. Universal precautions should be used with all athletes who have sustained injuries.</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

AHA, American Heart Association; EBV, Epstein-Barr virus; ECG, electrocardiogram; GI, gastrointestinal; LVEF, left ventricular ejection fraction; WPW, Wolff-Parkinson-White syndrome.
amnesia (PTA), and confusion. The pathophysiology is related to alterations in brain metabolism and the release of neurotransmitters.

Concussions have been categorized by many different grading systems, but recent consensus recommends all athletes should be removed from play until symptoms have resolved. Once symptoms have resolved a six-step progression is outlined for return to play: (1) assess at rest; once asymptomatic progress to (2) light aerobic exercise, followed by (3) sport-specific exercise, then begin (4) noncontact drills followed by (5) contact drills, and finally (6) release to game play. If any symptoms are present, the athlete should not move to the next step.

Preseason testing may help practitioners in assessing acute concussive status. Among commonly used assessment tools are the Standardized Assessment of Concussion (SAC), Balance Error Scoring System (BESS), computerized testing, and symptoms checklist (Table 25–4). Neuropsychology testing is advocated for athletes with persistent symptoms. Recent findings related to multiple concussions in athletes indicate that one concussion episode places an athlete at a higher risk for a repeat concussion, and that children with repeat concussions may have more severe injuries with protracted recovery times. In general, conservative return to play guidelines should be used in children.

2. Second Impact Syndrome

Second impact syndrome is a rare but potentially deadly complication of head injuries. Athletes who have had a prior brain injury that has not healed and have a second injury are at risk for a loss of vascular autoregulation and subsequent malignant cerebral edema.

3. Atlantoaxial Instability

Atlantoaxial instability is common in children with Down syndrome because of underlying ligamentous laxity, including the annular ligament of C1, and hypotonia. Cervical neck films including flexion, extension, and neutral position evaluate the atlanto-dens interval (ADI). ADI is normally less than 2.5 mm, but up to 4.5 mm is acceptable in this population. Children with an ADI greater than 4.5 mm should be limited from contact and collision activities.

Burners and stingers are common injuries in contact sports, especially football. These types of cervical radiculopathies or brachial plexopathies occur when the head is laterally bent and the shoulder depressed. Symptoms include immediate burning pain and paresthesias down one arm generally lasting only minutes. Weakness in the muscles of the upper trunk—supraspinatus, deltoid, and biceps—can persist for weeks. The most important part of the workup is a thorough neurologic assessment to differentiate this injury from a serious cervical spine injury. The key distinguishing feature of the stinger is its unilateral nature. If symptoms persist, then a diagnostic evaluation should include cervical spine radiographs, magnetic resonance imaging (MRI) scans, and electromyography.

Treatment consists of removal from play and observation. The athlete can return to play once symptoms have resolved, neck and shoulder range of motion is pain-free, reflexes and strength are normal, and the Spurling test is negative. Preventative strategies include always wearing protective gear, proper blocking and tackling techniques, and maintaining neck and shoulder strength.

Burners and stingers are common injuries in contact sports, especially football. These types of cervical radiculopathies or brachial plexopathies occur when the head is laterally bent and the shoulder depressed. Symptoms include immediate burning pain and paresthesias down one arm generally lasting only minutes. Weakness in the muscles of the upper trunk—supraspinatus, deltoid, and biceps—can persist for weeks. The most important part of the workup is a thorough neurologic assessment to differentiate this injury from a serious cervical spine injury. The key distinguishing feature of the stinger is its unilateral nature. If symptoms persist, then a diagnostic evaluation should include cervical spine radiographs, magnetic resonance imaging (MRI) scans, and electromyography.

Treatment consists of removal from play and observation. The athlete can return to play once symptoms have resolved, neck and shoulder range of motion is pain-free, reflexes and strength are normal, and the Spurling test is negative. Preventative strategies include always wearing protective gear, proper blocking and tackling techniques, and maintaining neck and shoulder strength.

Injuries to the spine are fairly common even in the pediatric population. As children have become more competitive in sports, the number of reported injuries has increased. Sports with a fairly high incidence of back injuries include golf, gymnastics, football, dance, wrestling, and weightlifting. Pain lasting more than 2 weeks indicates a possible structural problem and needs to be investigated.
Acute injury to the spine often results from an axial load injury. Patients present with focal tenderness of the thoracic or thoracolumbar spine. Evaluation includes plain radiography that may demonstrate mild wedging of the thoracic vertebra. When significant spinal tenderness or any neurological abnormalities are present, radiographs are often followed by computed tomography (CT) or MRI. Treatment of minor compression fractures includes pain control, bracing, rest from high-risk sports, and physical therapy. With appropriate rehabilitation, athletes can usually return to contact activity within 8 weeks.

1. Spondylolysis

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Injury to the pars interarticularis.
- Usually presents as back pain with extension.

Spondylolysis is an injury to the pars interarticularis. Pars defects are present in 4–6% of the population. The percentage of pars defects in athletes such as gymnasts, dancers, divers, and wrestlers is significantly increased. Repetitive overload results in stress fractures. Spondylolysis occurs at L5 in 85% of cases. The athlete presents with back pain that is aggravated by extension, such as arching the back in gymnastics. There may be palpable tenderness over the lower lumbar vertebrae, along with pain on the single leg hyperextension test. Tight hamstrings are another common physical examination finding. Evaluation includes anteroposterior (AP) and lateral radiographs of the lumbar spine. Although oblique radiographic views of the lumbar spine are helpful to look for the so-called Scottie dog sign, they are falling out of favor because they often fail to show the lesion. Single photon emission computed tomography scan, CT scan, and MRI can be useful to determine the presence of an active spondylolytic lesion.

Treatment includes refraining from hyperextension and high-impact sporting activities, stretching of the hamstrings, stabilization exercises, and lumbosacral bracing. Athletes can cross-train with low-impact activity and neutral or flexion-based physical therapy. Return to play is often delayed 6 weeks or longer based on clinical signs of healing. Surgery is reserved for refractory cases.

2. Spondylolisthesis

When a bilateral pars injury occurs, slippage of one vertebra over another causes a spondylolisthesis. These injuries are graded from 1 to 4 based on the percentage of slippage: grade 1 (0–25%), grade 2 (25–49%), grade 3 (50–74%), and grade 4 (75–100%). Patients present with hyperlordosis, kyphosis, pain with hyperextension, and in severe cases, a palpable step-off. Diagnosis is based on lateral radiographs.

Treatment is often symptom based. Asymptomatic athletes with less than 30% slippage have no restrictions and are followed on a routine basis. Slippage of 50% or more requires interventions of stretching hip flexors and hamstrings, working on core stability, along with bracing or surgery. If surgery is required, the athlete must understand that he or she cannot return to activities for at least a year and may not be able return to previous sporting activities.

3. Disk Herniation

Discogenic back pain accounts for a small percentage of back injuries in children. These injuries are almost unheard of in preadolescence. Back pain can originate from disk herniation, apophyseal injury, and disk degeneration. Most injuries occur at L4–L5 and L5–S1 vertebrae. Symptoms include back and leg pain. Pain may be increased with activities such as bending, sitting, and coughing. Pain often radiates down the lower extremity in a radicular pattern. Evaluation includes physical and neurologic examinations, including straight leg testing, sensory testing, and checking reflexes. If symptoms persist, evaluation includes electromyography, CT, and MRI scans.

Treatment usually is conservative as most back injuries improve spontaneously. The athlete can rest the back for a short period and then begin a structured exercise program of extension and isometrics followed by flexion exercises. If symptoms persist, a short course of steroids may be indicated. Surgery is recommended only if neurologic compromise persists.

**SHOULDER INJURIES**

Shoulder injury is usually a result of acute trauma or chronic overuse. Acute injuries around the shoulder include contusions, fractures, sprains (or separations), and dislocations. The age of the patient affects the injury pattern, as younger patients are more likely to sustain fractures instead of sprains.

1. Fracture of the Clavicle

Clavicular fractures occur from a fall or direct trauma to the shoulder. Focal swelling and tenderness are present over the clavicle. Diagnosis is made by radiographs of the clavicle; the fractures are most common in the middle third of the bone.

Initial treatment is focused on pain control and protection with a sling and swathe. Early range of motion is permitted, based on pain level. Progressive rehabilitation is important. Athletes cannot return to contact sports for 8–10 weeks. Surgical indications for acute clavicular fractures include open fractures or neurovascular compromise. Frac-
ture nonunion is unusual in young patients, but older adolescents with recurrent fractures or nonunion occasionally undergo surgical fixation.

2. Acromioclavicular Separation

A fall on the point of the shoulder is the most common cause of acromioclavicular separation. Tearing of the acromioclavicular joint capsule and possibly the coracoclavicular ligaments occurs. The injury is classified by the extent of the injuries to these ligaments. Athletes present with focal soft tissue swelling and tenderness over the acromioclavicular joint. More severe injuries are associated with deformity. Patients have a positive cross-arm test, in which pain is localized to the acromioclavicular joint. Radiographs are helpful to assess the degree of injury and to evaluate for a coexisting fracture.

Treatment is supportive, with rest and immobilization in a sling followed by progressive rehabilitation. Return to activity can be accomplished in 1–6 weeks depending on the severity of the injury. Full range of motion and full strength must be achieved.

3. Fracture of the Humerus

Fractures of the humerus occur from a severe blow or fall on the shoulder. Pain and swelling are localized to the proximal humeral region. The fractures can include the physes or may be extraphyseal. Some amount of displacement and angulation can be tolerated in this location because of the young athlete’s potential for remodeling. Careful assessment of the brachial plexus and radial nerves are needed to rule out associated nerve damage.

Treatment consists of a sling for 4–6 weeks followed by progressive rehabilitation.

4. Acute Traumatic Anterior Shoulder Instability (Anterior Shoulder Dislocation/Subluxation)

Injury can be acute or chronic.
- Pain is described as diffuse or anterior and lateral.
- Overhead activities exacerbate the pain.

Numerous shoulder injuries are related to repetitive overuse and tissue failure. Rotator cuff injuries are common in sports requiring require repetitive overhead motions. Muscle imbalances and injury can cause the position of the humeral head to be abnormal, which may cause impingement of the supraspinatus tendon under the acromial arch. Patients with nontraumatic shoulder instability due to ligamentous and capsular laxity (also known as multidirectional instability) are prone to overuse rotator cuff injury. The athlete presents with a chronic history of pain in the anterior and lateral shoulder, which is increased with overhead activities. Diagnostic workup includes plain radiographs and an outlet view to look for anatomic variability.

The rehabilitation of this injury is geared toward reduction of inflammation, improved flexibility, core stabilization, and strengthening of the scapular stabilizers and rotator cuff muscles. A biomechanics evaluation can assist athletes in the recovery process by building sport-specific skills and eliminating substitution patterns.

5. Rotator Cuff Injury

Injury with an abducted and externally rotated arm.
- Severe pain in the shoulder.
- Squared-off shoulder on examination.
- Reduced range of motion of the shoulder

Acute traumatic anterior shoulder instability occurs from a significant force applied to the abducted and externally rotated shoulder. Most often, the humeral head is dislocated in an anterior and inferior direction. The patient has severe pain and a mechanical block to motion. Patients require immediate closed reduction. Radiographs are helpful to confirm the position of the humeral head as well as to evaluate for coexisting fracture. MRI may be required for accurate visualization of fractures and cartilaginous injury.

Follow-up treatment for a glenohumeral dislocation in young athletes is controversial. Initially, the shoulder is immobilized for comfort. Range-of-motion exercises and progressive rehabilitation are initiated. Because of the high risk of recurrence, options for treatment should be individualized, with consideration given to both nonoperative and surgical management.

6. Little League Shoulder

Participation in a throwing sport.
- Pain with throwing.
- Pain in the lateral aspect of the humerus.
- Swelling around the shoulder.
- Widening of the proximal humeral physis on radiographs.
Proximal humeral epiphysitis, or “Little League shoulder,” is an overuse injury that occurs in children aged 11–14 years who play overhead sports such as baseball. The patient presents with activity-related pain in the lateral aspect of the proximal humerus. Examination often shows tenderness over the proximal humerus. However, benign findings on office examination do not preclude this diagnosis. The hallmark feature is pain with throwing. Radiographs show widening, sclerosis, and irregularity of the proximal humeral physis. Comparison views are often helpful when considering this diagnosis.

Treatment consists of rest from throwing or other aggravating activity. Physical therapy is initiated during the rest period. Return to play can only be accomplished after a period of rest has significantly decreased the pain and the athlete has proceeded through a progressive throwing program. Healing can take several months. Signs of radiographic healing may lag behind the athlete’s clinical progress, and normal radiographs are not necessarily required to return an athlete to play.

ELBOW & FOREARM INJURIES

Injuries in the forearm are quite common with both chronic and acute etiologies (eg, the chronic overuse “Little League elbow” and the frequent childhood fracture typical of falls on an outstretched arm). When evaluating the elbow, consider dividing the examination into specific anatomic areas as discussed below.

1. Medial Epicondylitis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Participation in a throwing sport.
- Pain over the medial condyles, especially with pitching.
- Swelling medial elbow.
- Elbow flexion contracture.

Medial epicondylitis, often called Little League elbow, encompasses a group of abnormalities that develop in young baseball pitchers secondary to the biomechanical forces generated around the elbow during throwing. These forces can result in shearing, inflammation, traction, and abnormal bone development. The symptoms are primarily swelling, pain, performance difficulties, and weakness. The pain localizes to the medial epicondyle, which may be tender to palpation. Wrist flexion and pronation increase symptoms. Workup includes a series of elbow radiographs, including comparison films, to look for widening of the epiphyseal lines and possibly MRI studies.

Treatment of the acute injury includes rest from throwing. It is not uncommon for a player to be benched for up to 6 weeks. Competition can be resumed once the player is asymptomatic. The key to treating this injury is prevention. Children should be properly conditioned and coached in correct throwing biomechanics. Guidelines for pitching limits in youth baseball have been developed. Little League limits 10- to 12-year-old children to 6 innings per week and 13- to 15-year-old children to 9 innings per week. Guidelines for limiting pitches per game are outlined in Table 25–5.

2. Panner Disease

Panner disease refers to variations in the normal ossification of the capitellum. This condition occurs in children aged 5–12 years who play sports that involve overhead throwing. The child may have dull aching in the lateral elbow that generally worsens when throwing. Swelling and reduced elbow extension usually are present. Radiographs show an abnormal capitellum, with fragmentation and areas of sclerosis.

Treatment is conservative, using rest, ice, and splinting. The child can return to play after radiographs normalize. The natural history of this condition is one of complete resolution of symptoms and ultimately normal ossification of the capitellum.

3. Osteochondritis Dissecans

Lateral elbow pain in a slightly older throwing athlete, usually aged 13–15 years, can be secondary to osteochondritis dissecans. Valgus compressive forces can lead to avascular necrosis of the capitellum, which can result in the formation of loose bodies. The athlete presents with lateral pain, swelling, lack of full extension, and occasionally locking. Radiographs and MRI can more fully delineate the lesion.

aBased on 2 games per week.
Treatment is based on classification and can be either conservative or surgical. The child should be seen by an orthopedic specialist with expertise in upper extremity injuries.

4. Lateral Epicondylitis

Lateral epicondylitis is common in skeletally mature athletes participating in racquet sports, particularly tennis. It is an overuse of the extensor muscle in the forearm and causes pain in the lateral elbow. Pain is increased by wrist extension.

Initial treatment is aimed at inflammation control. Stretching and strengthening of forearm muscles are the primary interventions during the subsequent phases. Stroke mechanics may need to be altered and a forearm brace used to decrease the forces in the extensor muscles.

5. Wrist Injury

Most swollen wrists without evidence of instability can be splinted for several weeks. Radial and ulnar fractures, which are fairly common in children, must be ruled out. Scaphoid fractures are caused by a force applied to a hyperextended wrist. If evidence of snuffbox tenderness and swelling is present, the wrist must be immobilized for 10 days and then reassessed, even if radiographs are normal. A nondisplaced fracture requires at least 6 weeks of immobilization in a thumb spica cast. Nonunion can occur, particularly in fractures of the proximal pole of the scaphoid, and is related to the poor blood supply to this carpal bone. Displacement requires operative management.

Hand & Wrist Injuries

All hand and wrist injuries have the potential for long-term, serious disability and deserve a thorough evaluation.

1. Distal Phalanx Injury

Tuft injury requires splinting for 6 weeks or until the patient is pain-free. If there is significant displacement, then a K-wire can be used for reduction. Nail bed injury often requires splinting and drainage of subungual hematomas.

2. Distal Interphalangeal Injury

Mallet finger or extensor tendon avulsion occurs in ball-handling sports. The mechanism of injury is a force applied to an extended finger. Treatment is splinting in extension for 6 weeks for fractures and 8 weeks for tendon rupture.

3. Thumb Injury

Gamekeeper's thumb is an injury to the ulnar collateral ligament from forced abduction of the metacarpophalangeal joint. It is a common skiing injury. If a radiograph shows an avulsed fragment is displaced less than 2 mm, a thumb spica cast can be used. If there is no fragment and less than 35 degrees of lateral joint space opening, a spica cast for 6 weeks is indicated. Surgery is required for more serious injuries.

4. Fractures

Boxer's fracture is a neck fracture of the fifth digit. These fractures can be treated by closed reduction and casting for 3 weeks. A displaced fracture requires open reduction and internal fixation.

5. Posterior Elbow Pain

Posterior elbow pain is uncommon. Etiologies include dislocations, fractures, triceps avulsions, olecranon apophysitis, and olecranon bursitis.

Hand & Wrist Injuries

Because the pelvis and hip articulate with both the lower extremities and the spine, this area is rich in ligaments, muscle attachments, and nerves. Injuries in young children are rare, but sprains, strains, and avulsion fractures are common. Additionally, athletes can be susceptible to overuse injury involving the hip.

1. Hip Avulsion Fractures

Avulsion fractures around the hip in adolescents occur at apophyseal regions such as the ischial tuberosity, anterior superior iliac spine, anterior inferior iliac spine, and iliac crest. The mechanism of injury is a forceful, unbalanced muscle contraction that causes avulsion of the muscle tendon insertion. The athlete presents with a history of an acute traumatic incident; often a “pop” is felt and the athlete is immediately unable to bear weight. Range of motion of the
782

CHAPTER 25

hip is limited secondary to pain, and focal tenderness is present over the apophysis. Treatment is conservative. It is rare for surgery to be required even in displaced fractures. The athlete can progress to weight bearing as tolerated. The rehabilitation phase focuses on regaining motion, flexibility training, and pelvic and core strengthening. Progressive return to activity can often be accomplished in 4–6 weeks if full range of motion, full strength, and sport-specific skills have been achieved.

2. Slipped Capital Femoral Epiphysis

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Pain in the hip or knee, or both.
- Loss of internal rotation of the hip.
- Radiographs in the frog-leg position show widening of the physis and epiphyseal slippage.

Slipped capital femoral epiphysis can occur in children aged 11–16 years. The physis is weakened during times of rapid growing and is susceptible to shearing failure. Patients complain of groin, thigh, or knee pain and often have a limp. Examination shows painful range of motion of the hip, limited internal rotation, and obligatory external rotation when the hip is flexed. Radiographs include AP and frog-leg lateral films, which demonstrate widening of the physis and the epiphyseal slippage.

Treatment consists of immediate non–weight bearing and urgent referral to an orthopedic specialist for open reduction and internal fixation. Rehabilitation is a component of the postsurgical treatment, and return to activity is progressive over months. (See also Chapter 24.)

3. Acetabular Labral Tears

Acetabular labral tears cause anterior hip pain. The injury often occurs from a twisting injury of the hip that tears the fibrocartilaginous ring around the acetabulum. Athletes present with deep anterior hip or groin pain that worsens with activity and is resistant to treatment. Radiographic findings can be normal. An MRI arthrogram is used to demonstrate the tear. Treatment starts conservatively and requires rest. Arthroscopy is reserved for recalcitrant cases.

4. Adductor Strain

An adductor strain or a groin pull is generally caused by forced abduction as in running, falling, twisting, or tackling. Sports that require quick directional changes place the athlete at risk for these types of injuries. The associated pain is in the adductor muscle. There is often pain with adduction or hip flexion and tenderness over the adductor tubercle. Treatment includes rest, ice, protection, and strengthening of the muscle when it heals. In severe cases the muscle can be immobilized in a spica cast until the muscle has a chance to heal.

5. Hamstring Strain

Hamstring strain is a common injury in athletes. The mechanism of injury is forced extension of the knee or directional changes. The classic scenario is an athlete who suddenly stops play, grabbing the back of the knee. There are three grades of injury. Examination reveals pain on palpation of the muscle. Pain also occurs with knee flexion against resistance.

Initial treatment is focused on minimizing swelling, bruising, and pain. The thigh should be iced and compression applied. In moderate and severe injuries crutches may be needed for a short duration. The athlete can walk as soon as he or she can tolerate the activity. It is particularly important to stretch the hamstring because, as a two-joint muscle, it is more susceptible to injury than other types of muscle. Eccentric strengthening is an important component of rehabilitation.

6. Quadriceps Contusion

Quadriceps contusion is caused by a direct injury to the muscle, resulting in bruising, swelling, and pain. The amount of damage is directly related to the amount of force. The anterior and lateral thigh regions are most commonly injured often in contact sports such as football and lacrosse.

Treatment is rest, ice, and protection for the first 24 hours. The knee should be kept in a fully flexed position. Two to three days after the injury, range-of-motion exercises may begin in both flexion and extension. Once 120 degrees of motion has been established and movement does not cause pain, the athlete may return to competitive activity. If the muscle remains firm on examination after 2 weeks, then radiographs of the thigh should be obtained to rule out myositis ossificans. **Myositis ossificans** is an abnormal deposition of calcium in the muscle that may be induced by aggressive stretching of the muscle too early in the clinical course.

7. Hip Dislocation

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Usually produces posterior dislocation.
- Leg is flexed, adducted, and externally rotated.
- Hip pain is severe.
- This is an on-site emergency and must be treated quickly.
The hip joint can be dislocated in forceful injuries. Most hip dislocations occur in the posterior direction. Athletes with this injury classically present with hip flexion, adduction, and internal rotation. Hip dislocations in skeletally mature athletes are almost always associated with acetabular and femoral neck fracture. The preadolescent, skeletally immature competitor may have an isolated injury. Hip radiographs and CT scan may be needed to completely evaluate the injury.

This is a true on-field emergency, and the athlete should be transported to the nearest facility that has an orthopedic surgeon available. Severe bleeding, avascular necrosis, and nerve damage can result. Once reduction has been established in an uncomplicated case, protected weight bearing on crutches for 6 weeks is recommended followed by another 6 weeks of range-of-motion and strengthening exercises. An athlete may return gradually to competition after 3 months, when strength and motion are normal.

8. Pelvic Apophysitis
Pelvic apophysitis occurs in adolescent athletes who are typically competitive and are participating consistently, often year round, in their sport. Common locations are the ischial tuberosity and iliac crest. The athlete presents with pain over the apophysis and pain with resisted hip motion specific to the muscle insertion. Radiographs can show irregularity over the apophysis, or be normal. Treatment consists of relative rest, progressive rehabilitation focusing on flexibility, and pelvis and core stabilization.

9. Iliotibial Band Syndrome
Iliotibial band syndrome and associated trochanteric bursitis can cause pain when the hip is flexed, often as a result of reduced flexibility of the iliotibial band and gluteus medius tendons. The bursa is a structure that allows for improved motion by reducing friction. When a bursa becomes inflamed, movement is painful and may be limited. Other areas susceptible to inflammation, besides the hip, are the shoulder, elbow, and patella. Iliotibial band syndrome is best evaluated in a side-lying position, and pain is reproduced when the hip is actively flexed from a fully extended hip (Ober test).

Initial treatment is to alter the offending activity and then start a stretching program geared at the iliotibial band and hip abductors. Ultrasound is beneficial and corticosteroid injections may be used after conservative treatment has failed.

10. Femoral Neck Fractures
Femoral neck fractures (stress fractures) are generally the result of repetitive microtrauma. They commonly occur in running athletes who have increased their mileage. Athletes with this type of injury present with persistent pain in the groin and pain with internal and external rotation. Range of motion may be limited in hip flexion and internal rotation. If plain radiographs are negative, an MRI or a bone scan is indicated.

Treatment is based on the type of fracture. A transverse fracture generally requires internal fixation to prevent femoral displacement and the risk of avascular necrosis. A compression fracture is less likely to be displaced; treatment is conservative and involves resting the hip until it heals. Cardiovascular conditioning can be maintained easily through nonimpact exercises and activity.
B. Patellar Tendonitis (“Jumper’s Knee”)
This overuse injury is caused by repetitive loading of the quadriceps during running or jumping. This diagnosis is common in basketball and volleyball athletes. Tenderness is located directly over the patellar tendon.

C. Osgood-Schlatter Disease (Tibial Tubercle Apophysitis)
This condition is caused by the recurrent traction on the muscle-tendon unit that occurs in jumping and running sports. Fragmentation and microfractures of the tibial tubercle occur during its time of rapid growth. The condition occurs in the preteen and adolescent years and is most common in boys aged 12–15 years and girls aged 11–13 years. Pain usually is present at the tibial tubercle, and is aggravated by activities using eccentric quadriceps muscle movement. The pain can become so extensive that routine activity must be curtailed. Radiographs typically demonstrate fragmentation or irregular ossification of the tibial tubercle.

Typically the condition resolves on its own. In the interim, pain control using NSAIDs is indicated. Stretching the hamstrings and application of ice after workouts is helpful.

D. Sinding-Larsen-Johansson Disease (Apophysitis of the Inferior Pole of the Patella)
This condition involves a process similar to that in Osgood-Schlatter disease, but occurring in younger athletes, usually between ages 9 and 12 years. Traction from the patellar tendon results in fragmentation of the inferior patella that is often obvious on a lateral knee radiograph.

3. Meniscal Injuries

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Posterior knee pain.
- Effusion and joint line tenderness.
- Feeling of locking or of the knee giving way.
- Positive McMurray test.

The meniscus of the knee cushions forces in the knee joint, increases nutrient supply to the cartilage, and stabilizes the knee. Most injuries are related to directional changes on a weight-bearing extremity. Medial meniscus injuries have a history of tibial rotation in a weight-bearing position. This happens frequently in ball-handling sports. Lateral meniscus injuries occur with tibial rotation with a flexed knee, as in exercises such as squatting or certain wrestling maneuvers. These injuries are uncommon in children younger than age 10 years.

Clinical Findings
The athlete with such an injury has a history of knee pain, swelling, snapping, or locking or may report a feeling of the knee giving way. Physical examination often reveals swelling, joint line tenderness, and a positive McMurray hyperflexion-rotation test. The diagnostic test of choice is MRI of the knee, although standard knee radiographs should be included.

Treatment
Treatment may be symptomatic for minor, isolated injuries of the meniscus that do not involve a mechanical block. Persistent loss of motion and other signs of meniscal damage suggest meniscal impingement and require more urgent referral for surgical management. Surgery is also indicated in failure of conservative care within 4–6 weeks of the injury. If surgery is needed, weight bearing may not be allowed, depending on the amount of meniscal damage and the type of repair required. Typically, however, range-of-motion and strengthening exercises can be resumed quickly, and return to play can be achieved within 4–6 weeks.

4. Medial & Lateral Collateral Ligament Injuries

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pain on the medial or lateral portion of the knee.
- Tenderness along the ligament.
- Positive valgus stress test at 0 and 30 degrees.
The medial and lateral collateral ligaments are positioned along either side of the knee and act to stabilize the knee during varus and valgus stress. Medial injuries occur either with a blow to the lateral aspect of the knee, as seen in a football tackle, or with a noncontact rotational stress.

**Clinical Findings**

The athlete may feel a “pop” or lose sensation along the medial aspect of the knee. The examination reveals an effusion and tenderness medially. A valgus stress test performed in 20–30 degrees of flexion reproduces pain.

Medial collateral ligament injuries are graded on a scale of 1 to 3. Grade 1 injuries represent a stretching injury. Grade 2 injury involves partial disruption of the ligament. Grade 3 injury is a complete disruption of the ligament. Radiographs are useful, especially in the skeletally immature athlete, to evaluate for distal femoral or proximal tibial bone injury. MRI scans are used if grade 3 injury or concomitant intra-articular derangement is suspected.

**Treatment**

Treatment is almost always conservative. Initial injuries should be iced and elevated. A protective brace needs to be worn, and full knee motion in the brace can be permitted within a few days. Weight bearing is allowed, and a strengthening program can be started. The athlete should use the brace until the pain and range of motion have improved. The use of a functional brace is often required when a player returns to competition. Bracing is temporary, until the ligament heals properly and the athlete has no subjective feelings of instability.

5. Anterior Cruciate Ligament Injuries

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Pain and effusion of the knee.
- Pain along the anterior joint line.
- Positive Lachman test.

The ACL consists of three bands that prevent anterior subluxation of the tibia. It is injured by deceleration, twisting, and cutting motions. The mechanism of injury involves force applied to the knee during hyperextension, with excessive valgus stress and forced external rotation of the femur on a fixed tibia.

**Clinical Findings**

The athlete often reports hearing or feeling a “pop,” followed by swelling that occurs within hours of the injury. Evaluation of the knee begins with examination of the uninjured knee.

The Lachman test provides the most accurate information about knee stability in relation to the ACL. All other structures of the knee need to be examined to rule out concomitant injuries. Imaging of the knee includes plain radiographs along with an MRI scan. In skeletally immature athletes, a tibial spine avulsion is often seen on radiographs rather than a midsubstance ACL tear.

**Treatment**

Initial treatment focuses on controlling swelling and pain management. Structured physical therapy can be instituted early to assist in regaining range of motion and strength. Treatment options include both conservative and surgical management. Conservative treatment includes bracing, strengthening, and restricting physical activity. Knee braces enhance proprioception and control terminal extension. Conservative management can be complicated by continued instability and damage to meniscal cartilage. Recent advances in surgical treatment of the skeletally immature athlete have been helpful in dealing with the complicated management of young athletes with ACL tears.

Surgical repair is typically indicated for young athletes in cutting sports and is also required for persistent instability. Surgery can be performed 2–6 weeks following the injury if the swelling and motion in the knee have improved. Rehabilitation of the knee starts immediately after surgery. A continuous passive range-of-motion machine is used postoperatively. Partial weight bearing is allowed in a brace that is set in full extension as the quadriceps strengthen. After 2 weeks, partial weight bearing and walking are started. The goals of the subsequent program are continued strength, muscle reeducation, endurance, agility, and coordination. Return to cutting and pivoting sports can be achieved by 6 months after surgery.

6. Posterior Cruciate Ligament Injuries

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Pain and swelling of the posterior knee.
- Increased pain with knee flexion.
- Positive posterior Drawer test.

The posterior cruciate ligament (PCL) runs from the medial femoral condyle to the posterior tibial plateau and has two parts. Its main function is to prevent posterior tibial subluxation. Injury to the PCL is uncommon; it occurs when the individual falls on a flexed knee with the ankle in plantarflexion or with forced hyperflexion of the knee. The most common sports in which PCL injuries are sustained are football and hockey.
CHAPTER 25

FOOT & ANKLE INJURIES

Injuries in the lower leg, ankle, and foot are quite common in pediatric athletes. The types of injuries sustained tend to depend on the age group. Young children tend to have diaphyseal injuries, in contrast to older children in rapid growth, who tend to have epiphyseal and apophyseal injuries. Skeletally mature adolescents are prone to adult-pattern ligamentous injury.

Although fractures of the ankle are possible with inversion and eversion mechanisms, the most common acute injury involving the ankle is the ankle sprain.

1. Ankle Sprain

Clinical Findings

The athlete presents with swelling and pain in the posterior and lateral knee. The examination begins with the uninjured knee and proceeds to the injured side. Confirmatory testing includes the posterior drawer test, performed with the patient supine, the knee flexed to 90 degrees, and the foot stabilized. Grading is based on the amount of translation. Grade 1 (mild) is up to 5 mm, grade 2 (moderate) is 5–10 mm, and grade 3 (severe) is more than 10 mm. Diagnostic imaging includes plain radiographs and MRI scan.

Treatment

Treatment can be determined as soon as the exact injury has been isolated. Treatment is controversial with respect to surgical versus nonsurgical management, although nonsurgical management is gaining popularity as outcomes tend to be similar for both groups.

Braces and a progressive rehabilitation program have been used successfully in athletes with grade 1 and 2 injuries. Athletes with grade 3 injuries and chronic instability may require surgery.

When a ligament is overloaded tearing occurs. These injuries are graded on a scale of 1 to 3. Grade 1 injury is a stretch without instability, grade 2 is a partial tear with some instability, and grade 3 is a total disruption of the ligament with instability of the joint. The ankle has three lateral ligaments (anterior talofibular, calcaneofibular, and posterior talofibular) and a medial deltoid ligament. Inversion of the foot generally damages the anterior talofibular ligament, whereas eversion injures the deltoid ligament. Lateral ankle sprains are far more common than medial ankle sprains because the deltoid ligament is stronger, mechanically, than the lateral ligaments.

Clinical Findings

Physical examination often reveals swelling, bruising, and pain. Diagnostic testing should be done when a bony injury is suspected. Obtaining radiographs is especially important when evaluating skeletally immature athletes who are more prone to growth plate injury.

The adult Ottawa criteria do not pertain to patients younger than age 18 years. Tenderness over the malleoli, tenderness beyond ligament attachments, and excessive swelling are reasons to obtain radiographs.

Differential Diagnosis

Other injuries to consider include injuries to the fifth metatarsal, which can occur with an inversion mechanism. In this injury, the athlete presents with localized swelling and tenderness over the base of the fifth metatarsal. Fractures at the base of the fifth metatarsal can be divided into avulsion, Jones, and diaphyseal fractures. Tibiofibular syndesmosis tear occurs with dorsiflexion and external rotation. Radiographs are required, and the squeeze test is positive. Fractures of the malleoli, fibula, talar dome or calcaneus may also mimic ankle sprain.

Treatment

Appropriate treatment of ligamentous ankle injuries is imperative to ensure full recovery and should begin immediately after the injury. Phase 1 care involves immediate compressive wrapping and icing to control swelling and inflammation. Protected weight bearing is allowed in the early phase of rehabilitation. Phase 2 begins when the athlete can ambulate without pain. During this time ankle range of motion is emphasized, along with isometric contractions of the ankle dorsiflexors. Once 90% of strength has returned, active isometric (eccentric and concentric exercises) and isokinetic exercises can be added. Phase 3 is designed to increase strength, improve proprioception, and add ballistic activity. The “foot alphabet” and “tilt board” are excellent methods to improve ankle proprioception. This program can be effective in returning athletes to activity within a few weeks, although up to 6 weeks may be required for return to full activity. The athlete should wear a protective brace for 3–4 months and continue to ice after exercising.
2. Sever Disease
Sever disease, or calcaneal apophysitis, occurs in athletes aged 9–12 years who are involved in high-impact activities such as gymnastics and soccer. Pain occurs at the point of muscle tendon insertion onto the growth center of the calcaneus. The athlete presents with activity-related heel pain, and examination reveals focal tenderness over the apophysis. Treatment consists of relative rest, heel cord stretching, ice massage and NSAIDS for pain control, and progression to activity as tolerated based on pain level.

3. Plantar Fasciitis
Plantar fasciitis is a common problem that manifests as heel pain in the adolescent or older athlete. It typically occurs in runners who log more than 30 miles per week and in athletes who have tight Achilles tendons or wear poorly fitting shoes. It is also common in people with cavus feet and in those who are overweight. The pain is worse upon first standing up in the morning and taking a few steps. A bone spur is often found on examination.

Treatment involves local massage, stretching of the gastrosoleus, NSAIDs, arch supports, and local steroid injections. Runners may need to cut back on their weekly mileage until these measures eliminate pain.

As in all activities, most sports-related injuries can be prevented by the use of protective equipment, common sense, and proper training. Protective equipment should be properly fitted and maintained by an individual with training and instruction. Helmets should be used in football, baseball, hockey, bicycling, skiing, in-line skating, skateboarding, or any sport with risk of head injury. Eye protection should be used in sports that have a high incidence of eye injuries. Proper protective padding should be identified and used, including chest pads for catchers; shin guards in soccer; shoulder, arm, chest, and leg padding in hockey; and wrist and elbow protectors in skating. A few common-sense concepts should be addressed by coaches, parents, and physicians in order to ensure the safety of children participating in sports. These include inspecting playing fields for potential hazards, adapting rules to the developmental level of the participants, and matching opponents equally.

The use of the preparticipation history and physical examination, described earlier, can identify potential problems and allow for prevention and early intervention. Proper training techniques reduce injuries by encouraging flexibility, promoting endurance, and teaching correct biomechanics. Sports education reinforces the concepts of fitness and a healthy lifestyle along with sport-specific training. Early identification of an injury allows the athlete to modify techniques and avoid micro- and macrotrauma. Once an injury has occurred, it needs to be identified properly and appropriate measures used to minimize inflammation. Rehabilitation of the injury starts as soon as it has been identified. Early and appropriate care offers the athlete an optimal chance for full recovery and return to full participation.

Rehabilitation medicine is the multispecialty discipline involved in the diagnosis and therapy of individuals with congenital and acquired disabilities. The overarching goals are to maximize the patient’s functional capabilities and improve quality of life. Disabilities are described using the World Health Organization’s International Classification of Function, Health, and Disability. Three aspects require evaluation in every patient: (1) the impact of the disability on body structure and function, (2) the impact of the disability on activity and participation, and (3) the environmental factors with an impact on patient function. Evaluation of these three areas provides a common framework for discussing a disabling condition and the impact it has on the body and on the individual’s ability to participate in society.

PEDIATRIC BRAIN INJURY

General Considerations

Every year there are an estimated 400,000 emergency department visits for brain injuries among children from birth through 14 years of age, with 3000 deaths and 29,000 hospitalizations. Children with brain injuries may have long-term deficits and disabilities that require identification and treatment. Brain injury is divided into primary and secondary injury.

Primary injury refers to the immediate injury causing focal or diffuse damage. Focal damage includes skull fracture, parenchymal bruising or contusion, extraparenchymal or intraparenchymal hemorrhage, blood clots, tearing of blood vessels, or penetrating injury. Diffuse damage includes diffuse axonal injury and edema. Consequences of primary injury, either focal or diffuse, include cellular disruption with release of excitatory amino acids, opiate peptides, and inflammatory cytokines.

Secondary injury refers to the loss of cellular function accompanying primary injury that results in loss of cerebrovascular regulation, altered cellular homeostasis, or cell death and functional dysregulation. A primary injury can initiate the processes of secondary programmed cell death (apoptosis), which further exacerbates the primary injury. Secondary injury may develop hours or days after the initial insult. It appears to be precipitated by elevated intracranial pressure, cerebral edema, and release of neurochemical mediators.

Clinical Classification & Severity Scores for Head Injury

Traumatic brain injury is usually categorized as open or closed. Open injuries are the result of penetration of the skull by missile or sharp object, or deformation of the skull with exposure of the underlying intracranial tissues. Closed injuries occur secondary to blunt trauma to the head, which causes movement (intracranial acceleration or deceleration and rotational forces) and compression of brain tissue. Brain contusions are referred to as coup (occurring at the site of injury) or contra-coup (occurring on the side of the brain opposite the injury). Measures for rating severity of injury and eventual outcomes are important in medical management. Included below are several common scales:

A. Glasgow Coma Scale

The Glasgow Coma Scale (GCS) is the most commonly used system to assess the depth and duration of impaired consciousness in the acute setting. The score is derived from three different areas of evaluation: motor responsiveness (maximum score 6), verbal performance (maximum score 5), and eye opening to stimuli (maximum score 6). The scale has been modified for use in infants and children younger than 5 years of age, allowing for their lack of verbal responsiveness and understanding (see Table 11–5). Cumulative scores on the GCS define injury as mild (13–15), moderate (9–12), and severe (≤ 8). The concept of post-traumatic amnesia is used to gauge severity of injury and is an adjunct to the GCS, termed the GCS-E (extended). Post-traumatic amnesia is defined as the period of time after an injury...
during which new memory cannot be incorporated and the person appears confused or disoriented. Amnesia can be retrograde, anterograde, or both.

B. Rancho Los Amigos Levels of Cognitive Function
The Rancho Los Amigos Levels of Cognitive Function (LCFS or “Rancho”) is commonly used to gauge the overall severity of cognitive deficit and can be used serially during recovery as a rough gauge of improvement. The scale has 10 levels of functioning ranging from “no response” to “purposeful, appropriate.”

C. Coma/Near Coma Score
The coma/near coma (CNC) score is a gauge of depth of coma for those with severe brain injury. It serves as a sensitive measure of clinical changes in sensory, perceptual, and primitive responses. Serial assessment of the patient’s coma status with the CNC can provide a means to track recovery and assess the potential for active participation in therapy.

Common Sequelae of Brain Injury
Depending on the severity of brain injury, there may be deficits in cognition and behavior, and a variety of physical impairments. Injuries can also produce changes in sensory and motor function, emotional stability, social behavior, mental processing speed, memory, speech, and language. The consequences of mild brain injuries may be difficult to discern. Small intraparenchymal injuries, easily identified by computed tomography (CT) or magnetic resonance imaging (MRI) scans, may not cause obvious signs or symptoms. The following are common problems associated with brain injury.

A. Seizures
Seizures occurring in the first 24 hours after injury are referred to as immediate seizures. Those occurring during the first week are delayed seizures, and those starting more than 1 week after injury are referred to as late seizures. Seizure prophylaxis with medications is recommended in the first week after brain injury in children at high risk for seizures and in very young children, who are at higher risk for early seizures than are older children and adults. Seizure prophylaxis is also recommended for 1 week after any penetrating brain trauma. Seizure prophylaxis is probably not effective for prevention of late-onset seizures. Late-developing seizures may require long-term treatment.

B. Motor Function Deficits
Motor function deficits after brain injury include movement disorders, spasticity, paralysis, and weakness. These deficits can result in impaired ambulation, coordination, impaired ability to use upper extremities, and speech problems. Physical therapy is the primary modality of treatment for these problems.

C. Sensory or Perceptual Deficits
Sensory deficits after traumatic brain injury are most commonly the result of cranial nerve injuries or parenchymal brain damage. Abnormal sensation may result in swallowing problems, reduced self-protective mechanisms, neglect, visual processing dysfunction, and pain.

D. Paroxysmal Autonomic Instability Associated with Dystonia
Severe brain injuries can be associated with autonomic dysfunction of the thalamus and hypothalamus, which results in a constellation of symptoms known as paroxysmal autonomic instability associated with dystonia (PAID). PAID is manifested by tachycardia, tachypnea, sweating, hyperthermia, agitation, and posturing. Common medications used in the treatment of PAID include dopamine agonists such as bromocriptine, β-blockers such as propranolol, and α-agonists such as clonidine.

E. Cognitive and Behavioral Deficits
After brain injury, cognitive and behavioral deficits may be obvious immediately or develop gradually. They include decreased arousal, decreased attention, impaired executive function, and problems with memory and concentration. Emotional lability, depression, agitation, impulsivity, and aggression can emerge. Many of these behaviors improve spontaneously, but some require behavioral or pharmacologic intervention.

F. Hypothalamic-Pituitary-Adrenal Axis Dysfunction
Dysfunction of the hypothalamic-pituitary-adrenal axis is common after head injury. The syndrome of inappropriate antidiuretic hormone secretion (SIADH) and diabetes insipidus from a posterior pituitary injury can result in significant electrolyte and osmolality imbalance and must be monitored closely. Amenorrhea is common in females and typically resolves spontaneously. Injury near the onset of puberty can complicate normal development, and endocrine status should be monitored closely.

G. Cranial Nerve Injuries
The sensory and motor components of the cranial nerves are often damaged, resulting in a wide variety of deficits not centrally mediated. Sight, hearing, taste, and smell, as well as swallowing, are among the most commonly affected functions. The vestibulocochlear nerve (cranial nerve VII) is most often affected followed by the oculomotor nerve (cranial nerve III). Hyposmia or anosmia (cranial nerve I) can occur if the shearing forces at the cribriform plate
disrupt the olfactory afferent nerves running centrally from the nose. Injury to cranial nerves III, IV, and VI can affect vision, causing diplopia and other deficits. Optic nerve (cranial nerve II) injury is relatively rare. If injury to the optic nerve occurs, it is usually apparent within 1 month of the initial traumatic event.

Developmental Considerations
Much of what we know of traumatic brain injury is based on experience in adults. The confounding effects of age and the etiologies unique to the pediatric population (eg, child abuse) make care of the pediatric head-injured patient very complex.

The assumption that younger children will fare better than older children or adults after a brain injury is a myth. The fact that, in a child, a significant amount of development and synaptic reorganization has yet to occur does not guarantee an improved chance for functional recovery. Indeed, disruption of developmental processes, especially in very young infants or neonates, may be catastrophic as these processes often cannot be resumed once disrupted.

The mechanism of injury plays an important role in determining the severity of brain injury in very young children. Mechanisms associated with nonaccidental injury such as shaking often result in global diffuse injury. The weak neck musculature, large head–to–body mass ratio, immature blood-brain barrier, and high intracranial fluid–to–brain mass ratio all contribute to widespread damage.

During puberty, major hormonal changes have an impact on the outcome of brain injury. Behavioral problems may be pronounced in brain-injured adolescents. Precocious puberty and precocious development of sexual activity may occur in preadolescents and should be carefully monitored.

Careful consideration should be given to the developmental progress of the brain-injured child and adolescent. Delays can be anticipated after moderate and severe brain injuries related to abnormalities of cognition and behavior. It is critical to identify developmental disabilities as early as possible so that appropriate therapy can be started in order to maximize the child’s residual capabilities. Educational programs should include an individualized educational program (IEP) to support the child with significant remediation and assistance needs during their school years. Programs should also include a 504 plan (named for Section 504 of the Rehabilitation Act and the Americans with Disabilities Act).

The 504 plan identifies the accommodations necessary in regular school settings for students with lesser disabilities so that they may be educated in a setting with their peers.

Treatment
The primary goal of rehabilitation after childhood brain injury is to maximize functional independence. Rehabilitative care can be divided into three phases: acute, subacute, and long term. The acute and subacute phases typically occur in the inpatient setting while the long-term phase is an outpatient endeavor.

A. Acute Care
Therapy in the acute phase consists mainly of medical, surgical, and pharmacological measures to decrease brain edema, treat increased intracranial pressure, and normalize serum laboratory values. Nutrition is essential in the healing process and either parenteral nutrition or supplemental enteral feedings are employed. Current research suggests that transitioning to enteral nutrition (eg, nasogastric tube feeding) as soon as possible after brain injury is associated with improved outcomes. Placement of a gastrostomy tube for supplemental enteral feeding is often performed in patients with severe brain injuries when recovery will be protracted and swallowing function is inadequate for safe oral feeding.

B. Subacute Care
Therapy in the subacute phase is characterized by early, intensive participation in rehabilitative therapies promoting functional recovery. Treatment should be planned after consultation with physical therapy, occupational therapy, speech-language specialists, and neuropsychologists. Nursing staff members are a primary interface with the patient and often serve as educators for family-directed care. Most children and adolescents with brain injuries can be discharged home to continue with treatment on an outpatient basis.

C. Long-Term Care
Long-term follow-up starts immediately after discharge. Medical issues must be thoroughly and regularly reviewed to ensure that changing needs are met. Annual multidisciplinary evaluation is important, especially as the child approaches school age. Neuropsychological testing may be required to define cognitive and behavioral deficits and plan strategies to deal with them in the educational environment. Therapies should be flexible, providing strategies to maximize independence and facilitate the child’s involvement in changing environments.

Medication is often required for cognitive and behavioral issues. Attention deficit, irritability, and fatigue associated with brain injury may be amenable to treatment with stimulants such as methylphenidate and modafinil. Dopaminergic agents such as amantadine, levodopa, and bromocriptine can be useful in improving cognition, processing speed, and agitation. Antidepressants such as selective serotonin reuptake inhibitors can be helpful in treating depression and mood lability. Anticonvulsants can be useful as mood stabilizers and in treating agitation and aggression. Tegretol and valproic acid are typical agents for this purpose.

Attention and arousal can also be successfully addressed by utilizing behavioral techniques to reinforce desired
behaviors as well as identifying environmental situations that optimize those behaviors. Gains made in the behavioral realm often have a positive impact on therapies designed to address physical issues.

**Prognosis & Outcomes**

Directly after brain injury, poor pupillary reactivity, low blood pH, absence of deep tendon reflexes, and low GCS all correlate with poor outcome. An increased number of intracranial lesions and increased depth and duration of coma are also associated with poor functional recovery. Children younger than 1 year of age tend to have worse outcomes.

Functional outcome assessment is important for judging the efficacy of rehabilitation therapy. Global multidomain measures are used to provide a functional “snapshot in time” of select functions—motor function and mobility, self-care, cognition, socialization, and communication. Several of these measures are available; the WeeFIM is the one most commonly used in pediatrics.

Outcome associated with mild brain injury is often quite favorable. Most patients recover normal function within a short time frame. A small percentage will develop persistent problems such as chronic headache, poor focusing ability, altered memory, and vestibular abnormalities.

In children, recovery may not be fully achieved for many months or years after the initial injury. The impact of the injury on developmental processes, and its future consequences, are difficult to predict. Long-term follow-up is required, particularly as the child approaches school age.

---

**SPINAL CORD INJURY**

**General Considerations**

Epidemiologic studies of spinal cord injuries (SCI) suggest that there will be about 10,000 new injuries per year and that 20% will be in children younger than age 20 years. Motor vehicle accidents are the leading cause of SCI in all ages. Falls are common causes in young children. The phenomenon of SCI without obvious radiologic abnormality (SCIWORA) can be present in 20–40% of young children. Children from birth to 2 years tend to have high-level injuries to the cervical spine because of the anatomical features of the spine in this age group. The facets tend to be shallower and oriented horizontally, and the boney spine is more flexible than the spinal cord. In addition the head is disproportionately large and the neck muscles are weak.

SCI are classified using the American Spinal Injury Association classification (ASIA class). This classification evaluates motor and sensory function, defines the neurologic level of the injury, and assesses the completeness of the deficit. The 72-hour ASIA examination is used in predicting recovery. A complete lesion identified on ASIA examination at 72 hours predicts a very poor recovery potential.

1. ASIA class A is a complete spinal cord injury, with no motor or sensory function in the lowest sacral segments.
2. ASIA class B is an incomplete injury, with preserved sensory function but no motor function in the sacral segments.
3. ASIA class C is an incomplete lesion in which the strength of more than 50% of key muscles below the injury level is graded less than 3/5 on manual muscle testing.
4. ASIA class D is an incomplete lesion in which the strength of more than 50% of key muscles below the injury level is graded greater than 3/5 on manual muscle testing.
5. ASIA class E is an injury in which full motor and sensory function is preserved.

**Clinical Findings**

**A. Clinical Patterns of Spinal Cord Injury**

1. **Brown-Séquard injury**—In this injury, the cord is hemisectioned, causing motor paralysis, loss of proprioception and vibration on the ipsilateral side and loss of pain and temperature on the contralateral side.
2. **Central cord syndrome**—Injury is to the central part of the cord and results in greater weakness in the arms than the legs.
3. **Anterior cord syndrome**—Disruption of the anterior spinal artery causes motor deficits and loss of pain and temperature sensation.
4. **Conus medullaris syndrome**—Injury or tumor of the conus causes minimal motor impairment but significant sensory and bowel and bladder abnormalities.
5. **Cauda equina syndrome**—Injury to the nerve roots produces flaccid bilateral weakness in the legs, sensory abnormalities in the perineum, and lower motor neuron bowel and bladder dysfunction.
B. Imaging

The diagnosis and anatomic description of SCI is made mainly through imaging techniques. Initial studies should include radiographs of the entire spine (including cervical spine) and special studies for boney structures. MRI imaging is required to evaluate soft tissues. CT scans, including three-dimensional reconstructions, may be used to further define the injured elements.

Treatment

A. Initial Management

The two primary precepts of SCI treatment are early identification and immediate stabilization of the spine. The approach used to stabilize the spine is determined by the type of injury, location of injury, and underlying condition of the spinal cord. Stabilizing the spine may prevent further damage to the spinal cord. External traction devices such as halo traction and orthotics are often used. Some injuries require internal stabilization. The benefit of corticosteroid administration in pediatric SCI has not been established but treatment is usually initiated based on adult data from the National Acute Spinal Cord Injury Study. The initial loading dose is 30 mg/kg over 15 minutes, followed by 5.4 mg/kg for the next 23 hours if started within 3 hours of injury. If started within 3–8 hours of injury, corticosteroids should be continued for 48 hours.

B. Functional Expectations after Spinal Cord Injury

The lesions associated with SCI have a predictable impact on motor and sensory function. It is helpful to understand these concepts when discussing functional expectations with patients and parents (Table 26–1).

C. Special Clinical Problems Associated with Spinal Cord Injury

1. Autonomic hyperreflexia or dysreflexia—This condition occurs in spinal injuries above the level of T6. Noxious stimuli in the injured patient cause sympathetic vasoconstriction below the level of injury. Vasoconstriction produces hypertension and then a compensatory, vagally mediated bradycardia. Symptoms therefore include hypertension, bradycardia, headaches, and diaphoresis. This response may be severe enough to be life threatening. Treatment requires identification and relief of the underlying noxious stimulus. Bowel, bladder, and skin problems are the most common noxious stimuli causing this syndrome. The patient should be placed in an upright position and antihypertensive medication used if conservative measures fail. Nifedipine (oral or sublingual) has been used in treatment of this condition.

Table 26–1. Functional expectations related to spinal cord injury.

</table>

*Level defined by sensory dermatome.
ADLs, activities of daily living; AFO, ankle-foot orthosis; KAFO, braces named for the joints being supported (ie, knee-ankle-foot orthosis); RGO, reciprocal gait orthosis.
2. Hypercalcemia—Hypercalcemia often occurs in male adolescents within the first 2 months of becoming paraplegic or tetraplegic. The serum calcium level rises significantly in response to immobilization. Patients complain of abdominal pain and malaise. Behavioral problems may occur. Initial treatment is focused on hydration and forced diuresis using fluids and furosemide to increase urinary excretion of calcium. In severe cases, especially in older children, calcitonin and etidronate may be required.

3. Thermoregulation problems—These problems are most common and most severe in higher level injuries and usually result in a poikilothermic state. The ability to vasoconstrict and vasodilate below the injury level is impaired. The person with an SCI above T6 is particularly susceptible to environmental temperature and is at risk for hypothermia and hyperthermia.

4. Deep vein thrombosis—Thrombosis is a common complication of SCI, especially in postpubescent children. Deep vein thrombosis should be suspected in children with any unilateral extremity swelling, palpable cords in the calf muscles, fevers, erythema, or leg pain. Diagnosis is confirmed by Doppler ultrasound, and full evaluation may require spiral CT scan or ventilation-perfusion scan if pulmonary embolus is suspected. Preventative measures include elastic stockings and compression devices. Anticoagulation medications include heparin and low-molecular-weight heparin (0.5 mg/kg every 12 hours).

5. Heterotopic ossification—This complication occurs in both spinal cord and traumatic brain injuries. Ectopic calcium deposits usually appear around joints in the first 6 months after injury. They may cause swelling, decreased range of motion, pain with motion, palpable firm masses, fever, elevated sedimentation rate, and abnormal triple phase bone scan. Etidronate therapy should be started at the time diagnosis. Surgical removal of ectopic deposits is controversial and usually performed only in cases of extreme loss of motion, pressure sores, or severe pain.

**Clinical Findings**

Erb palsy is characterized by shoulder weakness with internal rotation and adduction of the upper arm. The elbow is extended and the wrist flexed. There is good preservation of hand function. Klumpke palsy is characterized by good shoulder function but decreased or absent hand function. Brachial plexus injury may also cause Horner syndrome (unilateral miosis, ptosis and facial anhydrosis) due to disruption of cervical sympathetic nerves. Associated bony and nerve injuries are common in brachial plexus injury. The physical examination should include inspection of the humerus and clavicle for fractures. There may be injuries of the phrenic and facial nerves.

The diagnosis of a brachial plexus lesion should be based on the history and clinical examination. Diagnostic testing helps confirm, localize, and classify the lesion. Electromyography is helpful 3–4 weeks after the injury. This test not only is used diagnostically but can track recovery. MRI, myelography, and CT scan can help to locate the lesion and determine its extent.

**Treatment & Prognosis**

Primary surgery to the nerves of the plexus is indicated for children who have no spontaneous recovery of biceps function by 6–9 months. Secondary procedures to maximize function include muscle transfers and orthopedic interventions. Physical therapy is the major treatment for brachial plexus injury and includes stretching, bracing, and functional training.

The currently accepted method of predicting recovery is based on the spontaneous recovery of the biceps. Children in whom antigravity function returns within 2 months of injury will probably have near-full recovery of function. If antigravity function is delayed until 6 months after injury, recovery will probably be limited. If antigravity function is absent at 6–9 months after injury, there will be no recovery of function and surgical options to transplant muscles and improve motor function should be considered.
COMMON REHABILITATION PROBLEMS

1. Neurogenic Bladder

The function of the bladder is to hold and eventually expel urine. The muscles of the bladder include the detrusor and urethral sphincters. During the first year of life the bladder is a reflex-driven system that empties spontaneously. After the first year control begins to develop, and most children achieve continence by age 5 years. Children with damage to the central or peripheral nervous system may develop neurogenic bladder. Neurogenic bladder is usually classified as noted below.

1. Uninhibited neurogenic bladder occurs after upper motor neuron injuries at the level of the brain or SCI that result in failure to inhibit detrusor contractions. This results in a hyperreflexive voiding pattern.

2. Reflex neurogenic bladder results from damage to the sensory and motor nerves above the S3 and S4 level. The bladder empties reflexively but coordination may not be present and dyssynergia (contraction of the bladder musculature against a closed sphincter) can occur. Increased intravesicular pressure and vesicourethral reflux may be consequences of dyssynergia.

3. Autonomic neurogenic bladder is a flaccid bladder and is associated with lower motor neuron damage. Bladder volumes are usually increased and overflow incontinence can occur.

4. Motor paralytic neurogenic bladder results from injury to the motor nerves of the S2-4 roots. Sensation is intact but there is motor dysfunction. The child has the sensation to void but has difficulty with the voluntary contractions.

5. Sensory paralytic neurogenic bladder results when sensory roots are disrupted. Affected patients do not have sensation of the full bladder but are able to initiate voiding.

The diagnosis of neurogenic bladder requires a complete history and physical examination. The type of neurologic damage should be identified as this will help to predict anticipated voiding issues. The upper tracts should be assessed by several techniques, including ultrasound, intravenous pyelogram, and renogram (isotope) studies. Lower tract testing includes urinalysis, postvoid residuals, urodynamics, cystography, and cystoscopy.

Treatment

Treatment is geared to the type of bladder dysfunction. The simplest methods are those employing behavioral strategies. Timed voiding can be effective for children with uninhibited bladders. In this technique, children are reminded verbally or use a cueing device (watch with a timer) to void every 2–3 hours before bladder capacity is reached. The Credé and Valsalva maneuvers are used in patients with an autonomous bladder to assist in draining a flaccid bladder. There is a risk of increasing intravesicular pressure during these maneuvers, which can provoke vesicoureteral reflux. These maneuvers should never be used in a patient with a reflex neurogenic bladder.

Medications are often employed to treat neurogenic bladder. Anticholinergics are commonly used to reduce detrusor contractions, decrease the sense of urgency, and increase bladder capacity. Medications include oxybutynin, tolterodine, and hyoscyamine. The side effects of these medications include sleepiness, nausea, and constipation. Families often find these effects unacceptable and frequently abandon treatment.

External methods are also used to improve continence and function. Absorbent pads and diapers, external catheters, internal catheters, and clean intermittent catheterization are some typical methods. Surgical procedures to protect the upper tracts from urinary reflux are often used. A young child with a high-pressure bladder is at particular risk for reflux and may need medication, clean intermittent catheterization, or vesicostomy to prevent hydrostatic renal damage and infection. An older child may require bladder augmentation or an intestinal conduit from bladder to skin surface to relieve bladder distention (Mitrofanoff procedure). If there is an incompetent urethral sphincter with urinary leakage, injections, slings, or implants may be used to increase the urethral barrier. Recently, electrical stimulation of sacral roots has been used to initiate voiding. Biofeedback training is also used to improve voiding.

2. Neurogenic Bowel

Control of bowel function depends on an intact autonomic (sympathetic and parasympathetic) and somatic nervous system. Interruption of any of these pathways can result in bowel control problems. Goals of treatment for patients with neurogenic bowel are to establish a predictable and reliable bowel habit, prevent incontinence, and prevent complications. There are two types of neurogenic bowel dysfunction: upper motor and lower motor dysfunction. The upper neuron bowel results from damage above the conus. Affected patients usually have reflex bowel contractions of high amplitude, absence of sensation, and no voluntary sphincter control. Patients with the lower motor neuron bowel have no sphincter control and no anocutaneous reflex. It has been described as a flaccid bowel. In general establishing a bowel program is much easier in patients with the upper motor neuron–type lesion.

Diet

Diet is extremely important in either type of bowel program. Fiber and fluids are critical elements. Stool consistency should be on the soft side, although some patients try to keep themselves constipated to prevent accidents. A predictable and scheduled bowel program is essential. Bowel movements should be scheduled to occur with meals, as the gastrocolic reflex can trigger defecation.
Laxative and stool softening medications are usually included in a comprehensive bowel program. Stool softeners such as docusate retain stool water. Mineral oil is another acceptable stool softener in patients not at risk for pulmonary aspiration. Bulking agents such as Metamucil increase fiber and water content of stool and reduce transit time. Stimulants such as senna fruit extract or bisacodyl increase peristalsis. Osmotic agents such as polyethylene glycol keep stools soft by retaining stool water.

Suppositories and enemas are often used when other methods have not been successful. Upper motor neuron bowel management may require digital rectal stimulation as part of the program. Newer surgical options include sacral nerve stimulators and techniques to provide flushing of the colon. Cecostomy button or antegrade continence enema is employed when other conservative methods have not been able to achieve desired goals.

3. Spasticity

Spasticity is a velocity-dependent increase in muscle tone and a loss of isolated muscle function. Whereas tone is the resistance felt in a muscle as it is moved in space, spasticity occurs when there is damage to the central nervous system from trauma or injury. It is included in the upper motor neuron syndrome (hyperactive and exaggerated reflexes, increased tone, clonus, positive Babinski sign). Spasticity is evaluated using the Ashworth Scale, with zero indicating no increase in muscle tone and 4 indicating complete rigidity of the extremity.

Treatment

Treatment is goal directed and influenced by the functional status of the client. Spasticity has both positive and negative effects on quality of life. The positive aspects include the ability to use spasticity for functional tasks along with maintaining muscle strength. Negatively spasticity can interfere with positioning and hygiene, affect function, and can cause pain.

Options for therapy range from conservative to aggressive. A pyramidal approach starts from a base of prevention of nociceptive input and aggressive physical therapy. Children should be positioned properly and have appropriate equipment to support this strategy. Physical therapy is designed to reduce the long-term effects of spasticity by stretching and range-of-motion exercises. Heat and cold are useful in improving tone, but their effects are not long lived. Casting of both upper and lower extremities can decrease tone and increase range of motion. Constraint therapy can be used to try to improve upper extremity function.

The next step on the pyramid is the use of medications, mainly baclofen, diazepam, dantrolene, and tizanidine. Baclofen is a first-line medication, which produces effects at the spinal cord level. Side effects are mainly sleepiness and weakness. Seizure threshold may be reduced by baclofen. Baclofen can be delivered directly to the central nervous system through an intrathecal pump. It has been used successfully in children with brain injury, cerebral palsy, and SCI. Diazepam affects presynaptic GABA receptors in both the brain and the spinal cord. It can cause drowsiness and dependence. Dantrolene decreases the release of calcium in muscle. Side effects include weakness and, rarely, hepatotoxicity. Tizanidine is a newer agent and works at the α2-adrenergic receptors presynaptically. It can cause dry mouth and sedation, and liver function tests can be elevated.

Relief of focal spasticity can be achieved by using chemodenervation techniques. Botulinum toxin A and B can be injected in selected muscles to improve range of motion, thus improving function and hygiene as well as reducing pain and deformity. More recently, botulinum toxins have been used to treat drooling, hyperhydrosis, and chronic pain. These toxins block the release of acetylcholine at the neuromuscular junction. The effects are temporary, lasting only 3–6 months, and repeat injections are often needed. Phenol injections are another option for treatment of local spasticity and are technically more challenging. Phenol denatures proteins in both myelinated and unmyelinated fibers and produces neurolysis or myolysis, depending on the site of injection. The effects may last longer than botulinum toxins. Injections carry a risk of sensory dysesthesia if mixed nerves are injected.

Surgical options include orthopedic procedures geared toward improving function and ambulation and alleviating deformities produced over time by spasticity. Contractures are common in the Achilles tendon, hamstrings, and adductors. Upper extremity contractures occur in the elbow, wrist, and finger flexors. Scoliosis is fairly common and bracing or surgery may be needed. Gait analysis may be helpful in evaluating the child with functional spasticity as a guide for the use of orthotics, therapy, and surgery. Neurosurgical techniques such as selective dorsal rhizotomy are used in a very select group of children to permanently alter spasticity patterns and improve ambulation.
Rheumatic Diseases

Jennifer B. Soep, MD
J. Roger Hollister, MD

**Juvenile Idiopathic Arthritis**

### Essentials of Diagnosis & Typical Features

- Arthritis, involving pain, swelling, warmth, tenderness, morning stiffness, and decreased range of motion of one or more joints, lasting 6–12 weeks.
- May have associated systemic manifestations, including fever, rash, uveitis, serositis, anemia, fatigue, and growth failure.

### General Considerations

There are three classifications of juvenile chronic arthritis. These different systems of categorizing patients attempt to standardize the diagnosis and approach to patient care as well as assist in designing research protocols. Each classification contains three main subtypes: pauciarticular or oligoarticular, polyarticular, and systemic (Table 27–1). The exact cause of juvenile idiopathic arthritis (JIA) is not known, but there is substantial evidence that it is an autoimmune process with genetic susceptibility factors.

### Clinical Findings

**A. Symptoms and Signs**

The most common type of JIA is the pauciarticular/oligoarticular form, which affects 50% of patients and is characterized by arthritis of four or fewer joints. This type of JIA often affects medium to large joints. Because the arthritis is often asymmetrical, children may develop a leg-length discrepancy in which the involved leg grows longer due to increased blood flow and growth factors. The synovitis is usually mild and may be painless. Systemic features are uncommon except for inflammation in the eye. Up to 30% of children with this type of JIA develop insidious, asymptomatic uveitis, which may cause blindness if untreated. The activity of the eye disease does not correlate with that of the arthritis. Therefore, routine ophthalmologic screening with slit-lamp examination must be performed at 3-month intervals if the antinuclear antibody (ANA) test is positive, and at 6-month intervals if the ANA test is negative, for 4 years after the onset of arthritis.

Polyarticular disease is defined as arthritis involving five or more joints. This type of JIA affects 35% of patients. Both large and small joints are involved, typically in a symmetrical pattern. Systemic features are not prominent, although low-grade fever, fatigue, rheumatoid nodules, and anemia may be present. This group is further divided into rheumatoid factor-positive (10%) and rheumatoid factor-negative (25%) disease. The former resembles adult rheumatoid arthritis with more chronic, destructive arthritis.

The systemic form, also known as Still disease, is the least common form, comprising 10–15% of patients with JIA. The arthritis can involve any number of joints and affects both large and small joints, but may be absent at disease onset. One of the classic features is a high fever, often as high as 39–40°C, typically occurring one to two times per day. In between fever spikes the temperature usually returns to normal or subnormal. Ninety percent of patients have a characteristic evanescent, salmon-pink macular rash that is most prominent on pressure areas and when fever is present. Other systemic features that may be present, but are not specific for JIA, include hepatosplenomegaly, lymphadenopathy, leukocytosis, and serositis.

**B. Laboratory Findings**

There is no diagnostic test for JIA. A normal erythrocyte sedimentation rate (ESR) does not exclude the diagnosis of JIA. However, patients with systemic JIA typically have significantly elevated markers of inflammation including ESR, C-reactive protein (CRP), white blood cell count, and platelets. Rheumatoid factor is positive in about 10–15% of patients, usually when onset of polyarticular disease occurs after age 8 years. A newer test, anti–cyclic citrullinated
peptide (CCP) antibody, may be detectable prior to the rheumatoid factor and has a very high specificity for rheumatoid arthritis. ANA are associated with an increased risk of iridocyclitis in patients with oligoarticular disease. A positive ANA test is also fairly common in patients with the late-onset rheumatoid factor-positive form of the disease.

Table 27–2 lists the general characteristics of joint fluid in various conditions. The main indication for joint aspiration and synovial fluid analysis is to rule out infection. A positive Gram stain or culture is the only definitive test for infection. A leukocyte count over 2000/μL suggests inflammation; this may be due to infection, any of the collagen-vascular diseases, leukemia, or reactive arthritis. A very low glucose concentration (< 40 mg/dL) or very high polymorphonuclear leukocyte count (≥ 60,000/μL) is highly suggestive of bacterial arthritis.

C. Imaging

In the early stages of the disease, only soft-tissue swelling and periarticular osteoporosis are seen. Magnetic resonance imaging (MRI) of involved joints may show early joint damage and if obtained with gadolinium, can confirm the presence of synovitis. Later in the course of the disease, particularly in patients with rheumatoid factor-positive disease, plain films may demonstrate joint space narrowing due to cartilage thinning and erosive changes of the bone related to chronic inflammation.

Differential Diagnosis

Table 27–3 lists the most common causes of limb pain in childhood. JIA is a diagnosis of exclusion; therefore, it is important to rule out other causes of the clinical signs and symptoms prior to settling on this diagnosis. The differential diagnosis is often quite broad, including orthopedic conditions, infectious diseases, and malignancies. A few key features can help distinguish these different entities, including the timing of the pain and associated signs and symptoms. In inflammatory conditions, patients frequently have increased symptoms in the morning with associated stiffness. In contrast, patients with an orthopedic abnormality typically have increased symptoms throughout the day and with activity. Growing pains, a common cause of leg pain in childhood, are characterized by poorly localized pain at night, which frequently wakes the child from sleep; no objective signs of inflammation; and no daytime symptoms. Patients with growing pains often ask to be massaged, which is not typical of those with arthritis.

It is particularly important to establish the diagnosis in the case of monoarticular arthritis. Bacterial arthritis is usually acute and monoarticular except for arthritis associated with gonorrhea, which may be associated with a migratory pattern. Fever, leukocytosis, and increased ESR with an acute process in a single joint demand synovial fluid examination and culture to identify the pathogen. Pain in the hip or lower extremity is a frequent symptom of childhood cancer, especially leukemia, neuroblastoma, and rhabdomyosarcoma. Infiltration of bone by tumor and a joint effusion may be seen. Radiographs of the affected site and examination of the blood smear for unusual cells and thrombocytopenia are necessary. An elevated lactate dehydrogenase value should
also raise concern about an underlying neoplastic process. In doubtful cases, bone marrow examination is indicated.

In cases of reactive arthritis, a preceding illness is identified in approximately half of cases. Patients often have acute onset of arthritis, and there may be a migratory pattern. The duration of symptoms is very important to distinguish between reactive arthritides and JIA. Symptoms associated with reactive arthritis typically resolve within 4–6 weeks. In contrast, to meet criteria for chronic arthritis, symptoms must be present for at least 6–12 weeks.

The arthritis of rheumatic fever is migratory, transient, and often more painful than that of JIA. Rheumatic fever is very rare in children younger than 5 years of age. In suspected cases, evidence of rheumatic carditis should be sought based on examination and electrocardiographic findings. Evidence of recent streptococcal infection is essential to the diagnosis. The fever pattern in rheumatic fever is low grade and persistent compared with the spiking fever that characterizes the systemic form of JIA. Lyme arthritis resembles oligoarticular JIA, but the former occurs as discrete, recurrent episodes of arthritis lasting 2–6 weeks. For patients suspected of having Lyme disease, testing for antibodies against *Borrelia burgdorferi* should be performed, with confirmatory testing by Western blot.

### Treatment

The objectives of therapy are to restore function, relieve pain, maintain joint motion, and prevent damage to cartilage and bone.

#### A. Nonsteroidal Anti-Inflammatory Medications

First-line therapy is nonsteroidal anti-inflammatory drugs (NSAIDs). A wide range of agents is available but only a few are approved for use in children, including naproxen (10 mg/kg per dose twice daily), ibuprofen (10 mg/kg per dose three to four times daily), and meloxicam (0.125 mg/kg once daily). NSAIDs are generally well tolerated in children, as long as they are taken with food. The average time to symptomatic improvement is 1 month, but in some patients a response is not seen for 8–12 weeks.

#### B. Disease-Modifying and Biologic Agents

For patients with JIA who fail to respond to NSAIDs, weekly methotrexate is the second-line medication of choice. Symptomatic response usually begins within 3–4 weeks. The low dosages used (5–10 mg/m²/wk or 1 mg/kg/wk as a single dose) are generally well-tolerated. Potential side effects include nausea, vomiting, hair thinning, stomatitis, bone marrow suppression, and hepatotoxicity. A complete blood count and liver function tests should be obtained every 2–3 months. Several additional disease-modifying agents are available for use in patients with persistently active disease or those intolerant to methotrexate. Leflunomide is an antipyrimidine medication that has been shown to be as effective as methotrexate. Side effects may include diarrhea and alopecia. Medications that inhibit tumor necrosis factor, a cytokine known to play an important role in the pathogenesis of JIA, include etanercept, infliximab, and adalimumab. These drugs are generally quite effective in controlling disease and preventing cartilage and bone damage, and have been associated with healing based on radiologic changes. However, their potential long-term effects are unknown, and they are very expensive and require parenteral administration. Newer biologic agents, including anakinra, rituximab, and abatacept, have demonstrated some preliminary efficacy in patients who have not responded to other treatments.

#### C. Corticosteroids

Steroids are reserved for children with severe involvement, primarily patients with systemic disease. Local steroid joint
injections may be helpful in patients who have arthritis in one or a few joints. Triamcinolone hexacetonide is a long-acting steroid that can be used for injections and is often associated with at least several months of disease control.

D. Uveitis

Iridocyclitis should be closely monitored by an ophthalmologist. Typically treatment is initiated with corticosteroid eye drops and dilating agents to prevent scarring between the iris and the lens. In patients who fail topical treatments, methotrexate, cyclosporine, and infliximab may be used.

E. Rehabilitation

Physical and occupational therapy are important to focus on range of motion, stretching, and strengthening. These exercises, as well as other modalities such as heat, water therapy, and ultrasound, can help control pain, maintain and restore function, and prevent deformity and disability. Young children with oligoarticular disease affecting asymmetrical lower extremity joints can develop a leg-length discrepancy, which may require treatment with a shoe lift on the unaffected side.

Prognosis

The course and prognosis for JIA is variable, depending on the subtype of disease. Overall, the prognosis is good; 75–80% of patients remit without serious disability. In children with extended oligoarticular and polyarticular disease, more joints are involved; these patients may have more persistent and severe disease. Patients who are rheumatoid factor-positive are at highest risk for chronic, erosive arthritis that may continue into adulthood. The systemic features associated with systemic arthritis tend to remit within months to years. The prognosis in systemic disease is worse in patients with persistent systemic disease after six months, thrombocytosis and more extensive arthritis.

ENTHESITIS-RELATED ARTHRITIS & SPONDYLOARTHRITIS

Lower extremity arthritis, particularly in males older than 10 years of age, suggests a form of spondyloarthropathy. Inflammation of tendinous insertions (enthesopathy), such as the tibial tubercle or the heel, occurs in these diseases and not in JIA. Low back pain and sacroiliitis are commonly seen in this form of arthritis. Carriage of HLA-B27 antigen occurs in approximately 80% of patients with this disorder. No autoantibodies are found, but inflammatory indicators such as an elevated ESR or CRP may be present. Acute, not chronic, uveitis may occur.

NSAIDs, particularly indomethacin (2–4 mg/kg/d) and naproxen (15–20 mg/kg/d), are the first-line treatments for spondyloarthropathies. Refractory cases may respond to methotrexate, etanercept, or infliximab. Local corticosteroid injections are contraindicated in Achilles tendinitis. Unlike in adults, the disorder does not frequently progress to joint destruction or ankylosis in children.

ENTEROPATHIC ARTHRITIS

Enteropathic arthritis includes several syndromes, such as Reiter syndrome, reactive arthritis, and the arthritis of inflammatory bowel disease and celiac disease. Their unifying feature is the association of arthritis with preceding or concurrent gastrointestinal symptoms. Reactive arthritis that follows diarrhea caused by Salmonella, Shigella, or Yersinia infection occurs with increased frequency in individuals who are HLA-B27–positive. The arthritis associated with Crohn disease and ulcerative colitis usually begins after or concurrent with active bowel disease. Other extraintestinal manifestations such as uveitis, stomatitis, hepatitis, and erythema nodosum may occur in these individuals.

Treatment for the musculoskeletal manifestations of inflammatory bowel disease, in addition to controlling the bowel disease, is primarily NSAIDs. Patients who have persistent disease may require treatment with second-line agents such as methotrexate or infliximab (or both).

SYSTEMIC LUPUS ERYTHEMATOSUS

Essentials of Diagnosis & Typical Features

Multisystem inflammatory disease of the joints, serosal linings, skin, kidneys, blood, and central nervous system.

Autoantibodies such as ANA, double-stranded DNA, and anti-Smith antibodies are present and related to the pathogenesis of disease.

General Considerations

Systemic lupus erythematosus (SLE) is the prototype of immune complex diseases; its pathogenesis is related to the formation of antibody-antigen complexes that exist in the circulation and deposit in the involved tissues. The spectrum of symptoms is due to tissue-specific autoantibodies, as well
as damage to the tissue by lymphocytes, neutrophils, and complement evoked by the deposition of immune complexes. Laboratory tests for these antibodies and complement components give an objective assessment of disease activity and response to therapy. Autoreactive T lymphocytes that have escaped clonal deletion and unregulated B-lymphocyte production of autoantibodies may initiate the disease.

**Clinical Findings**

**A. Symptoms and Signs**

The onset of pediatric SLE is most common in girls between the ages of 9 and 15 years. Signs and symptoms depend on the organs affected by immune complex deposition. The American College of Rheumatology has established criteria to aid in the diagnosis of SLE; four of the following 11 criteria are necessary to establish the diagnosis:

1. Malar rash—photosensitive, so-called butterfly rash on the cheeks and nasal bridge.
2. Discoid rash—annular, scaly rash on the scalp, face, and extremities that can lead to scarring.
3. Photosensitivity—increased rash or other disease symptoms in response to sunlight exposure.
4. Mucous membrane ulcers—painless ulcers on the hard palate or nasal septum (or both).
5. Arthritis—nonerosive arthritis of large and small joints, typically in a symmetrical distribution.
6. Serositis—pericarditis or pleuritis (or both), often associated with chest pain and difficulty breathing.
7. Renal abnormalities—proteinuria (> 0.5 g/d) or cellular casts (or both).
8. Neurologic abnormalities—seizures or psychosis (or both).
9. Blood count abnormalities—low white blood cell count (< 4000/mm³), Coombs test–positive anemia and/or thrombocytopenia (< 100,000/mm³).
10. Positive ANA—seen in almost 100% of patients with SLE.
11. Autoantibodies—positive double-stranded DNA antibody, anti-Smith antibody, antiphospholipid antibodies, lupus anticoagulant, or false-positive blood test for syphilis.

Other common signs and symptoms include fever, fatigue, weight loss, anorexia, Raynaud phenomenon, myositis, vasculitis, chorea, neuropathies, depression, and cognitive changes.

**B. Laboratory Findings**

Complete blood count abnormalities are common, including leukopenia, anemia, and thrombocytopenia. Approximately 15% of patients are Coombs test–positive, but many patients develop anemia due to other causes, including chronic disease and blood loss. Patients with significant renal involvement may have electrolyte disturbances, elevated kidney function tests, and hypoalbuminemia. The ESR is frequently elevated during active disease. In contrast, many patients with active SLE have a normal CRP. When the CRP is elevated, it is important to investigate possible infectious causes, particularly bacterial infections. It is critical to monitor the urinalysis in patients with SLE for proteinuria and hematuria, as the renal disease may be otherwise clinically silent. In immune complex diseases, complement is consumed; therefore, levels of C3 and C4 are depressed with active disease.

The ANA test is positive in almost 100% of patients, usually at titers of 1:320 or above. In patients with suspected SLE, it is important to obtain a full ANA profile—including antibodies directed against double-stranded DNA, Smith, ribonucleic protein, and SSA and SSB antibodies—to better characterize their serologic markers of disease. Because approximately 50–60% of pediatric SLE patients have antiphospholipid antibodies and are therefore at increased risk of thrombosis, it is important to screen all patients with SLE for antiphospholipid antibodies and lupus anticoagulant.

**Differential Diagnosis**

Because there is such a wide spectrum of disease with SLE, the differential diagnosis is quite broad, including systemic JIA, mixed connective tissue disease (MCTD), rheumatic fever, vasculitis, malignancies, and bacterial and viral infections. A negative ANA test essentially excludes the diagnosis of SLE. Anti-double-stranded DNA and Smith antibodies are very specific for SLE. The preceding diagnostic criteria, which are very helpful in establishing the diagnosis of SLE, have a specificity and sensitivity of 96%.

MCTD, an overlap syndrome with features of several collagen-vascular diseases, shares many features with SLE. The symptom complex is diverse and often includes arthritis, fever, skin tightening, Raynaud phenomenon, muscle weakness, and rash. The ANA test is typically positive in very high titers. The ANA profile is negative except for antibodies directed against ribonucleic protein.

**Treatment**

The treatment of SLE should be tailored to the organ system involved so that toxicities may be minimized. Prednisone is the mainstay of treatment and has significantly lowered the mortality rate in SLE. Patients with severe, life-threatening, or organ-threatening disease are typically treated with intravenous pulse methylprednisolone, 30 mg/kg per dose (maximum of 1000 mg) daily for 3 days, and then switched to 2 mg/kg/d of prednisone. The dosage should be adjusted using clinical and laboratory parameters of disease activity, and the minimum amount of corticosteroid to control the disease should be used. Skin manifestations, arthritis, and fatigue may be treated with antimalarials such as hydroxychloroquine, 5–7 mg/kg/d orally. Pleuritic pain or arthritis can often be managed with NSAIDs.

If disease control is inadequate with prednisone or if the dose required produces intolerable side effects, a steroid-sparing
Dermatomyositis is a rare autoimmune disease of muscle and skin. The cause is unknown, but there are likely genetic and environmental factors predisposing to the condition.

Small arteries and veins are involved, with infiltrates of neutrophils, lymphocytes, plasma cells, and histiocytes. The lesion progresses to intimal proliferation and thrombus formation. These vascular changes are found in the skin, muscle, kidney, retina, and gastrointestinal tract. Post-inflammatory calcinosis may occur.

**Clinical Findings**

**A. Symptoms and Signs**

The predominant symptom is proximal muscular weakness, particularly affecting pelvic and shoulder girdle muscles. Tenderness, stiffness, and swelling may be found. Pharyngeal involvement, manifested as voice changes and difficulty swallowing, is associated with an increased risk of aspiration. Intestinal vasculitis can be associated with ulceration and perforation of involved areas. Flexion contractures and muscle atrophy may produce significant residual deformities. Calcinosis may follow the inflammation in muscle and skin.

Several characteristic rashes are seen in dermatomyositis. Patients often have a heliotrope rash on the upper eyelids, along with a malar rash that may be accompanied by edema of the eyelids and face. Gottron papules are shiny, erythematous, scaly plaques on the extensor surfaces of the knuckles, elbows, and knees. Nail-fold abnormalities, including dilation, thrombosis, and dropout of periungual capillaries, may identify patients with a worse prognosis.

**B. Laboratory Findings**

Determination of muscle enzyme levels, including aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, creatine phosphokinase, and aldolase, is helpful in confirming the diagnosis, assessing disease activity, and monitoring the response to treatment. Even in the face of extensive muscle inflammation, the ESR and CRP are frequently normal. An MRI scan of the quadriceps muscle can be used in equivocal cases to confirm the presence of inflammatory myositis. Electromyography is useful to distinguish myopathic from neurogenic causes of muscle weakness. Muscle biopsy is indicated in doubtful cases of myositis without the pathognomonic rash.

**Treatment**

Treatment is aimed at suppression of the inflammatory response and prevention of the loss of muscle function and joint range of motion. Acutely, it is very important to assess the adequacy of the ventilatory effort and swallowing and to rule out intestinal vasculitis. Corticosteroids are the initial therapy of choice. Treatment is usually initiated with prednisone, 2 mg/kg/d, and continued until signs and symptoms of active disease are controlled; the dosage is then gradually tapered. In severe cases, intravenous pulse methylprednisolone for 3 days is indicated. Therapy is guided by the physical examination findings and muscle enzyme values. Steroid therapy is generally maintained at the lowest dose possible for at
least 2 years to minimize the risk of exacerbations and calcinosis. If patients continue to have active disease, additional steroid-sparing agents such as methotrexate, cyclosporine, and in severe cases, cyclophosphamide, should be started.

Hydroxychloroquine and intravenous immunoglobulin are particularly helpful in managing the skin manifestations. As the rashes are photosensitive, sun protection is very important.

Physical and occupational therapy should be initiated early in the course of disease. Initially, passive range-of-motion exercises are performed to prevent loss motion. Later, once the muscle enzymes have normalized, a graduated program of stretching and strengthening exercises is introduced to restore normal strength and function.

**Course & Prognosis**

Most patients have a monocyclic course; 10–20% of patients have more chronic or recurrent symptoms. Factors that influence the outcome include the rapidity of symptom onset, extent of weakness, presence of cutaneous or gastrointestinal vasculitis, timeliness of diagnosis, initiation of therapy, and response to treatment. Dermatomyositis in children is not associated with an increased risk of cancer as it is in adults.

**SCLERODERMA**

Fortunately, the most common forms of scleroderma in childhood are localized morphea lesions and linear scleroderma, not the systemic disease. The skin disease begins as indurated, hyperpigmented or hypopigmented plaques (morphea) or linear bands (linear scleroderma) and ultimately leads to thickening and scarring of the involved areas. Patients may develop subcutaneous and muscular atrophy and joint contractures in underlying joints. Localized treatment with topical vitamin D analogues and ultraviolet light may be beneficial. Treatment with corticosteroids and methotrexate helps to limit extension of the disease and prevent the development of new lesions. Typically without treatment, the skin lesions progress over a 1–2-year period and then remit. No treatment is available to reverse the residual scarred areas; however, the skin tends to soften and develop more normal pigmentation over time.

In systemic sclerosis, the dermal process is generalized. Raynaud phenomenon is almost invariably present. Arthralgias, esophageal dysfunction, and renal disease are associated with systemic sclerosis. Involvement of the lungs, heart, and kidneys may lead to rapid deterioration. Supportive treatments should be initiated for the skin manifestations, Raynaud phenomenon, and gastrointestinal symptoms. Systemic immunosuppressant medications such as corticosteroids, methotrexate, and cyclophosphamide are used with variable response. Angiotensin-converting enzyme inhibitors are effective in preventing hypertensive renal crisis.

**RAYNAUD PHENOMENON**

Raynaud phenomenon is an intermittent vasospastic disorder of the extremities. As much as 10% of the adult population has this disorder, and onset in childhood is not uncommon. The classic triphasic presentation is cold-induced pallor, then cyanosis, followed by hyperemia, but incomplete forms are frequent. In adults older than 35 years who are ANA-positive, Raynaud phenomenon may be a harbinger of rheumatic disease. This progression is rarely seen in childhood. Evalu-
tion should include a detailed history with review of systems relevant to rheumatic disease and examination for nail-fold capillary abnormalities. In the absence of positive findings, Raynaud phenomenon is likely to be idiopathic.

Treatment involves education about keeping the extremities and core body warm and the role of stress, which may be a precipitant. In very symptomatic patients, treatment with calcium channel blockers such as nifedipine can be effective.

NONINFLAMMATORY PAIN SYNDROMES

1. Complex Regional Pain Syndrome

Complex regional pain syndrome, previously known as reflex sympathetic dystrophy, is a painful condition that is frequently confused with arthritis. Prevalence and recognition of the condition appear to be increasing. Severe extremity pain leading to nearly complete loss of function is the hallmark of the condition. Evidence of autonomic dysfunction is demonstrated by pallor or cyanosis, temperature differences (with the affected extremity cooler than surrounding areas), and generalized swelling. On examination, marked cutaneous hyperesthesia to even the slightest touch is evident. Results of laboratory tests are normal, without evidence of systemic inflammation. Radiographic findings are normal except for late development of osteoporosis. Bone scans may be helpful and may demonstrate either increased or decreased blood flow to the painful extremity.

The cause of this condition remains elusive. Unlike adults with this disorder, children infrequently have a preceding history of trauma. Treatment includes physical therapy to focus on restoration of function, maintenance of range of motion, and pain relief. NSAIDs can be helpful for pain control, and in patients with more chronic disease, gabapentin is frequently effective. Persistent disease may respond to local nerve blocks. Counseling is helpful to identify potential psychosocial stressors and to assist with pain management. Long-term prognosis is good if recovery is rapid; recurrent episodes imply a less favorable prognosis.

2. Fibromyalgia

Fibromyalgia is a chronic pain syndrome characterized by diffuse musculoskeletal pain, fatigue, sleep disturbance, and chronic headaches. Weather changes, fatigue, and stress exacerbate symptoms. Patients have normal examination findings except for characteristic trigger points at the insertion of muscles, especially along the neck, spine, and pelvis.

Treatment centers on physical therapy, non-narcotic pain medications, improving sleep, and counseling. Low-dose amitriptyline or trazodone can help with sleep and may produce remarkable reduction in pain. Physical therapy should emphasize a graded rehabilitative approach to stretching and exercise and promote regular aerobic exercise. Pregabalin recently became the first medication to be approved by the Food and Drug Administration for the treatment of fibromyalgia. Use of the drug is associated with decreased pain in adults with fibromyalgia, and future studies are planned to test the safety and efficacy of its use in children with the condition. The prognosis for children with fibromyalgia is not clear, and long-term strategies may be necessary to enable them to cope with the condition.

3. Hypermobility Syndrome

Ligamentous laxity, which previously was thought to occur only in Ehlers-Danlos syndrome or Down syndrome, is now recognized as a common cause of joint pain. Patients with hypermobility present with episodic joint pain and occasionally with swelling that lasts a few days after increased physical activity. Depending on the activity, almost any joint may be affected. Five criteria have been established: (1) passive opposition of the thumb to the flexor surface of the forearm, (2) passive hyperextension of the fingers so that they are parallel to the extensor surface of the forearm, (3) hyperextension of the elbow, (4) hyperextension of the knee, and (5) palms on floor with knees extended. Results of laboratory tests are normal. The pain associated with the syndrome is produced by improper joint alignment caused by the laxity during exercise. Treatment consists of a graded conditioning program designed to provide muscular support of the joints to compensate for the loose ligaments and to train patients on how to protect their joints from hyperextension.

REFERENCES

NORMAL HEMATOLOGIC VALUES

The normal ranges for peripheral blood counts vary significantly with age. Normal neonates show a relative polycythemia with a hematocrit concentration of 45–65%. The reticulocyte count at birth is relatively high at 2–8%. Within the first few days of life, erythrocyte production decreases, and the values for hemoglobin and hematocrit fall to a nadir at about 6–8 weeks. During this period, known as physiologic anemia of infancy, normal infants have hemoglobin values as low as 10 g/dL and hematocrits as low as 30%. Thereafter, the normal values for hemoglobin and hematocrit gradually increase until adult values are reached after puberty. Premature infants can reach a nadir hemoglobin level of 7–8 g/dL at 8–10 weeks.

Newborns have larger red cells than children and adults, with a mean corpuscular volume (MCV) at birth of more than 94 fL. The MCV subsequently falls to a nadir of 70–84 fL at about age 6 months. Thereafter, the normal MCV increases gradually until it reaches adult values after puberty. The normal number of white blood cells is higher in infancy and early childhood than later in life. Neutrophils predominate in the differential white count at birth and in the older child. Lymphocytes predominate (up to 80%) between about ages 1 month and 6 years.

Normal values for the platelet count are 150,000–400,000/μL and vary little with age.

BONE MARROW FAILURE

Failure of the marrow to produce adequate numbers of circulating blood cells may be congenital or acquired and may cause pancytopenia ( aplastic anemia) or involve only one cell line (single cytopenia). Constitutional and acquired aplastic anemias are discussed in this section and the more common single cytopenias in later sections. Bone marrow failure caused by malignancy or other infiltrative disease is discussed in Chapter 29. It is important to remember that many drugs and toxins may affect the marrow and cause single or multiple cytopenias.

Suspicion of bone marrow failure is warranted in children with pancytopenia and in children with single cytopenias who lack evidence of peripheral red cell, white cell, or platelet destruction. Macrocytosis often accompanies bone marrow failure. Many of the constitutional bone marrow disorders are associated with a variety of congenital anomalies.

CONSTITUTIONAL APLASTIC ANEMIA (FANCONI ANEMIA)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Progressive pancytopenia.
- Macrocytosis.
- Multiple congenital anomalies.
- Increased chromosome breakage in peripheral blood lymphocytes.

General Considerations

Fanconi anemia is a syndrome characterized by defective DNA repair that is caused by a variety of genetic mutations. Inheritance is autosomal recessive, and the disease occurs in all ethnic groups. Hematologic manifestations usually begin with thrombocytopenia or neutropenia and subsequently progress over the course of months or years to pancytopenia. Typically the diagnosis is made between ages 2 and 10 years.

Clinical Findings

A. Symptoms and Signs

Symptoms are determined principally by the degree of hematologic abnormality. Thrombocytopenia may cause purpura,
petechiae, and bleeding; neutropenia may cause severe or recurrent infections; and anemia may cause weakness, fatigue, and pallor. Congenital anomalies are present in at least 50% of patients. The most common include abnormal pigmentation of the skin (generalized hyperpigmentation, café-au-lait or hypopigmented spots), short stature with delicate features, and skeletal malformations (hypoplasia, anomalies, or absence of the thumb and radius). More subtle anomalies are hypoplasia of the thenar eminence or a weak or absent radial pulse. Associated renal anomalies include aplasia, so-called horseshoe kidney, and duplication of the collecting system. Other anomalies are microcephaly, microphthalmia, strabismus, ear anomalies, and hypogenitalism.

B. Laboratory Findings
Thrombocytopenia or leukopenia typically occurs first, followed over the course of months to years by anemia and progression to severe aplastic anemia. Macrocytosis is virtually always present, is usually associated with anisocytosis and an elevation in fetal hemoglobin levels, and is an important diagnostic clue. The bone marrow reveals hypoplasia or aplasia. The diagnosis is confirmed by the demonstration of an increased number of chromosome breaks and rearrangements in peripheral blood lymphocytes. The use of diepoxybutane to stimulate these breaks and rearrangements provides a sensitive assay that is virtually always positive in children with Fanconi anemia, even before the onset of hematologic abnormalities.

Specific molecular markers or genes (Fanc-A, B, C, and others) found in different ethnic populations are identified in research laboratories and are not available as routine clinical tests.

Differential Diagnosis
Because patients with Fanconi anemia frequently present with thrombocytopenia, the disorder must be differentiated from idiopathic thrombocytopenic purpura (ITP) and other more common causes of decreased platelets. In contrast to patients with ITP, those with Fanconi anemia usually exhibit a gradual fall in the platelet count. Counts less than 20,000/μL are often accompanied by neutropenia or anemia, along with phenotypical features. Fanconi anemia may also be manifested initially by pancytopenia, and must be differentiated from acquired aplastic anemia and other disorders, such as acute leukemia. Examination of the bone marrow and chromosome studies of peripheral blood lymphocytes (chromosomal breakage) will usually distinguish between these disorders.

Complications
The most important complications of Fanconi anemia are those related to thrombocytopenia and neutropenia. Endocrine dysfunction may include growth hormone deficiency, hypothyroidism, or impaired glucose metabolism. In addition, persons with Fanconi anemia have a significantly increased risk of developing malignancies, especially acute nonlymphocytic leukemia, head and neck cancers, genital cancers, and myelodysplastic syndromes. Death is usually the result of thrombocytopenic hemorrhage, overwhelming infection, or malignancy.

Treatment
Attentive supportive care is a critical feature of management. Patients with neutropenia who develop fever require prompt evaluation and parenteral broad-spectrum antibiotics. Transfusions are important, but should be used judiciously, especially in the management of thrombocytopenia, which frequently becomes refractory to platelet transfusions as a consequence of alloimmunization. Transfusions from family members should be discouraged because of the negative effect on the outcome of bone marrow transplantation. At least 50% of patients with Fanconi anemia respond, albeit incompletely, to oxymetholone, and many recommend institution of androgen therapy before transfusions are needed. However, oxymetholone is associated with hepatotoxicity, hepatic adenomas, and masculinization, and is particularly troublesome for female patients.

Successful bone marrow transplantation cures the aplastic anemia and is an important treatment option for children with Fanconi anemia who have a human leukocyte antigen (HLA)–identical sibling donor. Before transplantation the prospective donor must be screened for Fanconi anemia by chromosome breakage testing.

Prognosis
Many patients succumb to bleeding, infection, or malignancy in adolescence or early adulthood. The long-term outlook after successful bone marrow transplantation is uncertain, particularly with regard to the risk of subsequently developing malignancies.

ACQUIRED APLECTIC ANEMIA

Weakness and pallor.
- Petechiae, purpura, and bleeding.
- Frequent or severe infections.
- Pancytopenia with hypocellular bone marrow.
General Considerations

Acquired aplastic anemia is characterized by peripheral pancytopenia with a hypocellular bone marrow. Approximately 50% of cases in childhood are idiopathic. Other cases are secondary to idiosyncratic reactions to drugs such as phenylbutazone, sulfonamides, nonsteroidal anti-inflammatory drugs, and anticonvulsants. Toxic causes include exposure to benzene, insecticides, and heavy metals. Infectious causes include viral hepatitis (usually non-A, non-B, non-C), infectious mononucleosis, and human immunodeficiency virus (HIV). In immunocompromised children, aplastic anemia has been associated with human parvovirus B19. Immune mechanisms of marrow suppression are suspected in most cases.

Clinical Findings

A. Symptoms and Signs

Weakness, fatigue, and pallor result from anemia; petechiae, purpura, and bleeding occur because of thrombocytopenia; and fevers due to generalized or localized infections are associated with neutropenia. Hepatosplenomegaly and significant lymphadenopathy are unusual.

B. Laboratory Findings

Anemia is usually normocytic, with a low reticulocyte count. The white blood cell count is low, with a marked neutropenia. The platelet count is typically below 50,000/μL, and is frequently below 20,000/μL. Bone marrow aspiration and biopsy show hypocellularity, often marked.

Differential Diagnosis

Examination of the bone marrow usually excludes pancytopenia caused by peripheral destruction of blood cells or by infiltrative processes such as acute leukemia, storage diseases, and myelofibrosis. Many of these other conditions are associated with hypoplasmenogegy. Preleukemic conditions also may present with pancytopenia and hypocellular bone marrows. Cytogenetic analysis of the marrow is helpful, because a clonal abnormality may predict the subsequent development of leukemia. Since congenital anomalies may not be apparent in some children with Fanconi anemia, patients with newly diagnosed aplastic anemia should be studied for chromosome breaks and rearrangements in peripheral blood lymphocytes.

Complications

Acquired aplastic anemia is characteristically complicated by infection and hemorrhage, which are the leading causes of death. Other complications are those associated with therapy.

Treatment

Comprehensive supportive care is most important in the management of acute acquired aplastic anemia. Febrile illnesses require prompt evaluation and usually parenteral antibiotics. Red blood cell transfusions alleviate symptoms of anemia. Platelet transfusions may be lifesaving, but they should be used sparingly because many patients eventually develop platelet alloantibodies and become refractory to platelet transfusions.

Bone marrow transplantation is generally considered the treatment of choice for severe aplastic anemia when an HLA-compatible sibling donor is available. Because the likelihood of success with transplantation is influenced adversely by multiple transfusions, HLA typing of family members should be undertaken as soon as the diagnosis of aplastic anemia is made. Increasingly patients who lack HLA-matched siblings are able to find matched donors through cord blood banks or the National Marrow Donor Program.

An alternative to bone marrow transplantation from an HLA-matched sibling donor is immunomodulation, usually with antithymocyte globulin and cyclosporine. Responses are very good. Most patients show hematologic improvement and become transfusion-independent.

Prognosis

Children receiving early bone marrow transplantation from an HLA-identical sibling have a long-term survival rate of greater than 80%. Sustained, complete remissions may be seen in 65–80% of patients receiving immunosuppressive therapy. However, both therapies are associated with an increased risk of myelodysplastic syndromes, acute leukemia, and other malignancies in long-term survivors.

ANEMIAS

ANEMIAS

COMPENDIUM OF THERAPIES

APPROACH TO THE CHILD WITH ANEMIA

Anemia is a relatively common finding, and identifying the cause is important. Even though anemia in childhood has many causes, the correct diagnosis can usually be established with relatively little laboratory cost. Frequently the cause is identified with a careful history. The possibility of nutritional causes should be addressed by inquiry about dietary intake; growth and development; and symptoms of chronic disease, malabsorption, or blood loss. Hemolytic disease may
be associated with a history of jaundice (including neonatal jaundice) or by a family history of anemia, jaundice, gall-bladder disease, splenomegaly, or splenectomy. The child’s ethnic background may suggest the possibility of certain hemoglobinopathies or of deficiencies of red cell enzymes, such as glucose-6-phosphate dehydrogenase (G6PD). The review of systems may reveal clues to a previously unsuspected systemic disease associated with anemia. The patient’s age is important because some causes of anemia are age-related. For example, patients with iron-deficiency anemia and β-globin disorders present more commonly at ages 6–36 months than at other times in life.

The physical examination may also reveal clues to the cause of anemia. Poor growth may suggest chronic disease or hypothyroidism. Congenital anomalies may be associated with constitutional aplastic anemia (Fanconi anemia) or with congenital hypoplastic anemia (Diamond-Blackfan anemia). Other disorders may be suggested by the findings of petechiae or purpura (leukemia, aplastic anemia, hemolytic-uremic syndrome), jaundice (hemolysis or liver disease), generalized lymphadenopathy (leukemia, juvenile rheumatoid arthritis, HIV infection), splenomegaly (leukemia, sickle hemoglobinopathy syndromes, hereditary spherocytosis, liver disease, hypersplenism), or evidence of chronic or recurrent infections.

The initial laboratory evaluation of the anemic child consists of a complete blood count (CBC) with differential and platelet count, review of the peripheral blood smear, and a reticulocyte count. The algorithm in Figure 28–1 uses limited laboratory information, together with the history and physical examination, to reach a specific diagnosis or to focus additional laboratory investigations on a limited diagnostic category (eg, microcytic anemia, bone marrow failure, pure red cell aplasia, or hemolytic disease). This diagnostic scheme depends principally on the MCV to determine whether the anemia is microcytic, normocytic, or macrocytic, according to the percentile curves of Dallman and Siimes (Figure 28–2).

Although the incidence of iron deficiency in the United States has decreased significantly with improvements in infant nutrition, it remains an important cause of microcytic anemia, especially at ages 6–24 months. A trial of therapeutic iron is appropriate in such children, provided the dietary history is compatible with iron deficiency and the physical examination or CBC count does not suggest an alternative cause for the anemia. If
this is not the case, or if a trial of therapeutic iron fails to correct the anemia and microcytosis, further laboratory evaluation is warranted.

Another key element of Figure 28–1 is the use of both the reticulocyte count and the peripheral blood smear to determine whether a normocytic or macrocytic anemia is due to hemolysis. Typically hemolytic disease is associated with an elevated reticulocyte count, but some children with chronic hemolysis initially present during a period of virus-induced aplasia when the reticulocyte count is not elevated. Thus, review of the peripheral blood smear for evidence of hemolysis (eg, spherocytes, red cell fragmentation, sickle forms) is important in the evaluation of children with normocytic anemias and low reticulocyte counts. When hemolysis is suggested, the correct diagnosis may be suspected by specific abnormalities of red cell morphology or by clues from the history or physical examination. Autoimmune hemolysis is usually excluded by direct antiglobulin testing. Review of blood counts and the peripheral blood smear in such cases is important because signs of hemolytic disease suggest chronic hemolysis complicated by an aplastic crisis due to parvovirus infection. Appreciation of this phenomenon is important because chronic hemolytic disease may not be diagnosed until the anemia is exacerbated by an episode of red cell aplasia and subsequent rapidly falling hemoglobin level. In such cases, cardiovascular compromise and congestive heart failure may develop quickly.

 PURE RED CELL APLASIA

Infants and children with normocytic or macrocytic anemia, a low reticulocyte count, and normal or elevated numbers of neutrophils and platelets should be suspected of having pure red cell aplasia. Examination of the peripheral blood smear in such cases is important because signs of hemolytic disease suggest chronic hemolysis complicated by an aplastic crisis due to parvovirus infection. Appreciation of this phenomenon is important because chronic hemolytic disease may not be diagnosed until the anemia is exacerbated by an episode of red cell aplasia and subsequent rapidly falling hemoglobin level. In such cases, cardiovascular compromise and congestive heart failure may develop quickly.
1. Congenital Hypoplastic Anemia (Diamond-Blackfan Anemia)

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Age: birth to 1 year.
- Macrocytic anemia with reticulocytopenia.
- Bone marrow with erythroid hypoplasia.
- Short stature or congenital anomalies in one third of patients.

**General Considerations**

Diamond-Blackfan anemia is a relatively rare cause of anemia that usually presents in infancy or early childhood. Early diagnosis is important because treatment with corticosteroids results in increased erythropoiesis in about two thirds of patients, thus avoiding the difficulties and complications of long-term chronic transfusion therapy. The cause is unclear; both autosomal dominant and autosomal recessive modes of inheritance occur.

**Clinical Findings**

A. Symptoms and Signs

Signs and symptoms are generally those of chronic anemia, such as pallor; congestive heart failure sometimes follows. Jaundice, splenomegaly, or other evidence of hemolysis is usually absent. Short stature or other congenital anomalies are present in one third of patients. A wide variety of anomalies have been described; those affecting the head, face, and thumbs are the most common.

B. Laboratory Findings

Diamond Blackfan anemia is characterized by severe macrocytic anemia and marked reticulocytopenia. The neutrophil count is usually normal or slightly decreased, and the platelet count is normal or elevated. The bone marrow usually shows a marked decrease in erythroid precursors but is otherwise normal. In older children, fetal hemoglobin levels are usually increased and there is evidence of persistent fetal erythropoiesis, such as the presence of the i antigen on erythrocytes. In addition, the level of adenosine deaminase in erythrocytes is elevated.

**Differential Diagnosis**

The principal differential diagnosis is transient erythroblastopenia of childhood. Children with Diamond-Blackfan anemia generally present at an earlier age, often have macrocytosis, and have evidence of fetal erythropoiesis and an elevated level of red cell adenosine deaminase. In addition, short stature and congenital anomalies, are not associated with transient erythroblastopenia. Lastly, transient erythroblastopenia of childhood usually resolves within 6–8 weeks of diagnosis, whereas Diamond-Blackfan anemia is a lifelong affliction. Other disorders associated with decreased red cell production such as renal failure, hypothyroidism, and the anemia of chronic disease need to be considered.

**Treatment**

Oral corticosteroids should be initiated as soon as the diagnosis of Diamond-Blackfan anemia is made. Two thirds of patients will respond to prednisone, 2 mg/kg/d, and many of those who respond subsequently tolerate significant tapering of the dose. Patients who are unresponsive to prednisone require chronic transfusion therapy, which inevitably causes transfusion-induced hemosiderosis and the need for chelation with parenteral deferoxamine. Bone marrow transplantation is an alternative therapy that should be considered for transfusion-dependent patients who have HLA-matched siblings. Hematopoietic growth factors have been used in some cases with limited success. Unpredictable, spontaneous remissions occur in up to 20% of patients.

**Prognosis**

The prognosis for patients responsive to corticosteroids is generally good, particularly if remission is maintained with low doses of alternate-day prednisone. Patients dependent on transfusion are at risk for the complications of hemosiderosis, including death from congestive heart failure, cardiac arrhythmias, or hepatic failure. This remains a significant threat, particularly during adolescence, when compliance with nightly subcutaneous infusions of deferoxamine is often difficult to ensure.

2. Transient Erythroblastopenia of Childhood

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Age: 6 months to 4 years.
- Normocytic anemia with reticulocytopenia.
- Absence of hepatosplenomegaly or lymphadenopathy.
- Erythroid precursors initially absent from bone marrow.
CHAPTER 28

General Considerations

Transient erythroblastopenia of childhood is a relatively common cause of acquired anemia in early childhood. The disorder is suspected when a normocytic anemia is discovered during evaluation of pallor or when a CBC is obtained for another reason. Because the anemia is due to decreased red cell production, and thus develops slowly, the cardiovascular system has time to compensate. Therefore, children with hemoglobin levels as low as 4–5 g/dL may look remarkably well. The disorder is thought to be autoimmune in most cases, because IgG from some patients has been shown to suppress erythropoiesis in vitro.

Clinical Findings

Pallor is the most common sign, and hepatosplenomegaly and lymphadenopathy are absent. The anemia is normocytic, and the peripheral blood smear shows no evidence of hemolysis. The platelet count is normal or elevated, and the neutrophil count is normal or, in some cases, decreased. Early in the course, no reticulocytes are identified. The Coombs test is negative, and there is no evidence of chronic renal disease, hypothyroidism, or other systemic disorder. Bone marrow examination shows severe erythroid hypoplasia initially; subsequently, erythroid hyperplasia develops along with reticulocytosis, and the anemia resolves.

Differential Diagnosis

Transient erythroblastopenia of childhood must be differentiated from Diamond-Blackfan anemia, particularly in infants younger than age 1 year. In contrast to Diamond-Blackfan anemia, transient erythroblastopenia is not associated with macrocytosis, short stature, or congenital anomalies, or with evidence of fetal erythropoiesis prior to the phase of recovery. Also in contrast to Diamond-Blackfan anemia, transient erythroblastopenia is associated with normal levels of red cell adenosine deaminase. Transient erythroblastopenia of childhood must also be differentiated from chronic disorders associated with decreased red cell production, such as renal failure, hypothyroidism, and other chronic states of infection or inflammation. As with other single cytopenias, the possibility of malignancy (ie, leukemia) should always be considered, particularly if fever, bone pain, hepatosplenomegaly, or lymphadenopathy is present. In such cases, examination of the bone marrow is generally diagnostic. Confusion may sometimes arise when the anemia of transient erythroblastopenia is first identified during the early phase of recovery when the reticulocyte count is high. In such cases, the disorder may be confused with the anemia of acute blood loss or with hemolytic disease. In contrast to hemolytic disorders, transient erythroblastopenia of childhood is not associated with jaundice or peripheral destruction of red cells.

Treatment & Prognosis

By definition, this is a transient disorder. Some children require red cell transfusions if cardiovascular compromise is present. Resolution of the anemia is heralded by an increase in the reticulocyte count, which generally occurs within 4–8 weeks of diagnosis. Transient erythroblastopenia of childhood is not treated with corticosteroids because of its short course.

NUTRITIONAL ANEMIAS

1. Iron-Deficiency Anemia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pallor and fatigue.
- Poor dietary intake of iron (ages 6–24 months).
- Chronic blood loss (age > 2 years).
- Microcytic hypochromic anemia.

General Considerations

Long considered the most common cause of anemia in pediatrics, iron deficiency has decreased substantially in incidence due to improved nutrition and the increased availability of iron-fortified infant formulas and cereals. Thus, the current approach to anemia in childhood must take into consideration a relatively greater likelihood of other causes.

Normal-term infants are born with sufficient iron stores to prevent iron deficiency for the first 4–5 months of life. Thereafter, enough iron needs to be absorbed to support the needs of rapid growth. For this reason, nutritional iron deficiency is most common between 6 and 24 months of life. A deficiency earlier than age 6 months may occur if iron stores at birth are reduced by prematurity, small birth weight, neonatal anemia, or perinatal blood loss or if there is subsequent iron loss due to hemorrhage. Iron-deficient children older than age 24 months should be evaluated for blood loss. Iron deficiency, in addition to causing anemia, has adverse effects on multiple organ systems. Thus, the importance of identifying and treating iron deficiency extends past the resolution of any symptoms directly attributable to a decreased hemoglobin concentration.

Clinical Findings

A. Symptoms and Signs

Symptoms and signs vary with the severity of the deficiency. Mild iron deficiency is usually asymptomatic. In infants with more severe iron deficiency, pallor, fatigue, irritability, and delayed motor development are common. Children
whose iron deficiency is due in part to ingestion of unfortified cow’s milk may be fat, with poor muscle tone. A history of pica is common.

**B. Laboratory Findings**

The severity of anemia depends on the degree of iron deficiency, and the hemoglobin level may be as low as 3–4 g/dL in severe cases. Red cells are microcytic and hypochromic, with a low MCV and low mean corpuscular hemoglobin. The red blood cell distribution width is typically elevated, even with mild iron deficiency. The reticulocyte count is usually normal or slightly elevated, but the reticulocyte index or absolute reticulocyte count is decreased. Iron studies show a decreased serum ferritin and a low serum iron, elevated total iron-binding capacity, and decreased transferrin saturation. These laboratory abnormalities are usually present with moderate to severe iron deficiency, but mild cases may be associated with variable laboratory results. The peripheral blood smear shows microcytic, hypochromic red blood cells with anisocytosis, and occasional target, teardrop, elliptical, and fragmented red cells. Leukocytes are normal, and very often platelet count is increased with normal morphology.

The bone marrow examination is not helpful in the diagnosis of iron deficiency in infants and small children because little or no iron is stored as marrow hemosiderin at these ages.

**Differential Diagnosis**

The differential diagnosis is that of microcytic, hypochromic anemia. The possibility of thalassemia (α-thalassemia, β-thalassemia, and hemoglobin E disorders) should be considered, especially in infants of African, Mediterranean, or Asian ethnic background. In contrast to infants with iron deficiency, those with thalassemia generally have an elevated number of erythrocytes (the index of the MCV divided by the red cell number is usually less than 13) and are less likely, in mild cases, to have an elevated red blood cell distribution width. Thalassemias are associated with normal or increased levels of serum iron and ferritin and with normal iron-binding capacity. The hemoglobin electrophoresis in β-thalassemia minor typically shows an elevation of hemoglobin A₂ levels, but coexistent iron deficiency may lower the percentage of hemoglobin A₂ into the normal range. Hemoglobin electrophoresis will also identify children with hemoglobin E, a cause of microcytosis common in Southeast Asians. In contrast, the hemoglobin electrophoresis in α-thalassemia trait is normal. Lead poisoning has also been associated with microcytic anemia, but anemia with lead levels less than 40 mg/dL is often due to coexistent iron deficiency.

The anemia of chronic inflammation or infection is normocytic but in late stages may be microcytic. This anemia is usually suspected because of the presence of a chronic systemic disorder. The level of serum iron is low, but the iron-binding capacity is normal, and the serum ferritin level is normal or elevated. Relatively mild infections, particularly during infancy, may cause transient anemia. As a result, caution should be exercised when the diagnosis of mild iron deficiency is entertained in infants and young children who have had recent viral or bacterial infections. Ideally, screening tests for anemia should not be obtained within 3–4 weeks of such infections.

**Treatment**

The recommended oral dose of elemental iron is 6 mg/kg/d in three divided daily doses. Mild cases may be treated with 2 mg/kg/d given once daily before breakfast. Parenteral administration of iron is rarely necessary. Iron therapy results in an increased reticulocyte count within 3–5 days, which is maximal between 5 and 7 days. The hemoglobin level begins to increase thereafter. The rate of hemoglobin rise is inversely related to the hemoglobin level at diagnosis. In moderate to severe cases, an elevated reticulocyte count 1 week after initiation of therapy confirms the diagnosis and documents compliance and response to therapy. When iron deficiency is the only cause of anemia, adequate treatment usually results in a resolution of the anemia within 4–6 weeks. Treatment is generally continued for a few additional months to replenish iron stores.

---

**2. Megaloblastic Anemias**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- **Pallor and fatigue.**
- **Nutritional deficiency or intestinal malabsorption.**
- **Macrocytic anemia.**
- **Megaloblastic bone marrow changes.**

**General Considerations**

Megaloblastic anemia is a macrocytic anemia caused by deficiency of cobalamin (vitamin B₁₂), folic acid, or both. Cobalamin deficiency due to dietary insufficiency may occur in infants who are breast fed by mothers who are strict vegetarians or who have pernicious anemia. Intestinal malabsorption is the usual cause of cobalamin deficiency in children and occurs with Crohn disease, chronic pancreatitis, bacterial overgrowth of the small bowel, infection with the fish tapeworm (*Diphyllobothrium latum*), or after surgical resection of the terminal ileum. Deficiencies due to inborn errors of metabolism (transcobalamin II deficiency
and methylmalonic aciduria) also have been described. Malabsorption of cobalamin due to deficiency of intrinsic factor (pernicious anemia) is rare in childhood.

Folic acid deficiency may be caused by inadequate dietary intake, malabsorption, increased folate requirements, or some combination of the three. Folate deficiency due to dietary deficiency alone is rare but occurs in severely malnourished infants and has been reported in infants fed goat’s milk not fortified with folic acid. Folic acid is absorbed in the jejunum, and deficiencies are encountered in malabsorptive syndromes such as celiac disease. Anticonvulsion medications (eg, phenytoin and phenobarbital) and cytotoxic drugs (eg, methotrexate) also have been associated with folate deficiency, caused by interference with folate absorption or metabolism. Finally, folic acid deficiency is more likely to develop in infants and children with increased requirements. This occurs during infancy because of rapid growth and also in children with chronic hemolytic anemia. Premature infants are particularly susceptible to the development of the deficiency because of low body stores of folate.

Clinical Findings

A. Symptoms and Signs

Infants with megaloblastic anemia may show pallor and mild jaundice as a result of ineffective erythropoiesis. Classically, the tongue is smooth and beefy red. Infants with cobalamin deficiency may be irritable and may be poor feeders. Older children with cobalamin deficiency may complain of paresthesias, weakness, or an unsteady gait and may show decreased vibratory sensation and proprioception on neurologic examination.

B. Laboratory Findings

The laboratory findings of megaloblastic anemia include an elevated MCV and mean corpuscular hemoglobin. The peripheral blood smear shows numerous macro-ovalocytes with anisocytosis and poikilocytosis. Neutrophils are large and have hypersegmented nuclei. The white cell and platelet counts are normal with mild deficiencies, but may be decreased in more severe cases. Examination of the bone marrow typically shows erythroid hyperplasia with large erythroid and myeloid precursors. Nuclear maturation is delayed compared with cytoplasmatic maturation, and erythropoiesis is ineffective. The serum indirect bilirubin concentration may be slightly elevated.

Children with cobalamin deficiency have a low serum vitamin B₁₂ level, but decreased levels of serum vitamin B₁₂ may also be found in about 30% of patients with folic acid deficiency. The level of red cell folate is a better reflection of folate stores than is the serum folic acid level. Serum levels of metabolic intermediates (methylmalonic acid and homocysteine) may help establish the correct diagnosis. Elevated methylmalonic acid levels are consistent with cobalamin deficiency, whereas elevated levels of homocysteine occur with both cobalamin and folate deficiency.

Differential Diagnosis

Most macrocytic anemias in pediatrics are not megaloblastic. Other causes of an increased MCV include drug therapy (eg, anticonvulsants, anti-HIV nucleoside analogues), Down syndrome, an elevated reticulocyte count (hemolytic anemias), bone marrow failure syndromes (Fanconi anemia, Diamond-Blackfan anemia), liver disease, and hypothyroidism.

Treatment

Treatment of cobalamin deficiency due to inadequate dietary intake is readily accomplished with oral supplementation. Most cases, however, are due to intestinal malabsorption and require parenteral treatment. In severe cases, parenteral therapy may induce life-threatening hypokalemia and require supplemental potassium. Folic acid deficiency is treated effectively with oral folic acid in most cases. Children at risk for the development of folic acid deficiencies, such as premature infants and those with chronic hemolysis, are often given folic acid prophylactically.

Anemia of Chronic Disorders

Anemia is a common manifestation of many chronic illnesses in children. In some instances, causes may be mixed. For example, children with chronic disorders involving intestinal malabsorption or blood loss may have anemia of chronic inflammation in combination with nutritional deficiencies of iron, folate, or cobalamin. In other settings, the anemia is due to dysfunction of a single organ (eg, renal failure, hypothyroidism), and correction of the underlying abnormality resolves the anemia.

1. Anemia of Chronic Inflammation

Anemia is frequently associated with chronic infections or inflammatory diseases. The anemia is usually mild to moderate in severity, with a hemoglobin level of 8–12 g/dL. In general, the severity of the anemia corresponds to the severity of the underlying disorder, and there may be microcytosis, but not hypochromia. The reticulocyte count is low. The anemia is thought to be due to inflammatory cytokines that inhibit erythropoiesis, and shunting of iron into, and impaired iron release from, reticuloendothelial cells. Levels of erythropoietin are relatively low for the severity of the anemia. The serum iron concentration is low, but in contrast to iron deficiency, anemia of chronic inflammation is not associated with elevated iron-binding capacity and is associated with an elevated serum ferritin level. Treatment consists of correction of the underlying disorder, which, if controlled, generally results in improvement in hemoglobin level.

2. Anemia of Chronic Renal Failure

Severe normocytic anemia occurs in most forms of renal disease that have progressed to renal insufficiency. Although white cell and platelet production remain normal, the bone marrow shows significant hypoplasia of the erythroid series and the reticulocyte count is low. The principal mechanism is deficiency of erythropoietin, a hormone produced in the kidney, but other factors may contribute to the anemia. In the presence of significant uremia, a component of hemolysis may also be present. Recombinant human erythropoietin (epoetin alfa) corrects the anemia, largely eliminating the need for transfusions.

3. Anemia of Hypothyroidism

Some patients with hypothyroidism develop significant anemia. Occasionally, anemia is detected before the diagnosis of the underlying disorder. A decreased growth velocity in an anemic child suggests hypothyroidism. The anemia is usually normocytic or macrocytic, but it is not megaloblastic and, hence not due to deficiencies of cobalamin or folate. Replacement therapy with thyroid hormone is usually effective in correcting the anemia.

General Considerations

Hereditary spherocytosis is a relatively common inherited hemolytic anemia that occurs in all ethnic groups but is most common in persons of northern European ancestry, in whom the incidence is about 1:5000. The disorder is a heterogeneous one, marked by variable degrees of anemia, jaundice, and splenomegaly. In some persons, the disorder is mild and there is no anemia because erythroid hyperplasia fully compensates for hemolysis. Severe cases are transfusion-dependent prior to splenectomy. The hallmark of hereditary spherocytosis is the presence of microspherocytes in the peripheral blood. The disease is inherited in an autosomal dominant fashion in about 75% of cases; the remaining cases are thought to be autosomal recessive or to be caused by new mutations.

Hereditary spherocytosis is usually the result of a partial deficiency of spectrin, an important structural protein of the red cell membrane skeleton. Spectrin deficiency weakens the attachment of the cell membrane to the underlying membrane skeleton and causes the red cell to lose membrane surface area. This process creates spherocytes that are poorly deformable and have a shortened life span because they are trapped in the microcirculation of the spleen and engulfed by splenic macrophages. The extreme heterogeneity of hereditary spherocytosis is related directly to variable degrees of spectrin deficiency. In general, children who inherit spherocytosis in an autosomal dominant fashion have less spectrin deficiency and mild or moderate hemolysis. In contrast, those with nondominant forms of spherocytosis tend to have greater deficiency of spectrin and more severe anemia.

Clinical Findings

A. Symptoms and Signs

Hemolysis causes significant neonatal hyperbilirubinemia in 50% of affected children. Splenomegaly subsequently develops in the majority and is often present by age 5 years. Jaundice is variably present and in many patients may be noted only during infection. Patients with significant chronic anemia may complain of pallor, fatigue, or malaise. Intermittent exacerbations of the anemia are caused by increased hemolysis or by aplastic crises, and may be associated with severe weakness, fatigue, fever, abdominal pain, or even heart failure.

B. Laboratory Findings

Most patients have mild chronic hemolysis with hemoglobin levels of 9–12 g/dL. In some cases, the hemolysis is fully compensated and the hemoglobin level is in the normal...
range. Rare cases of severe disease require frequent transfusions. The anemia is usually normocytic and hyperchromic, and many patients have an elevated mean corpuscular hemoglobin concentration. The peripheral blood smear shows numerous microspherocytes and polychromasia. The reticulocyte count is elevated, often higher than might be expected for the degree of anemia. White blood cell and platelet counts are usually normal. The osmotic fragility is increased, particularly after incubation at 37°C for 24 hours. Serum bilirubin usually shows an elevation in the unconjugated fraction. The DAT is negative.

**Differential Diagnosis**

Spherocytes are frequently present in persons with immune hemolysis. Thus, in the newborn, hereditary spherocytosis must be distinguished from hemolytic disease caused by ABO or other blood type incompatibilities. Older patients with autoimmune hemolytic anemia frequently present with jaundice and splenomegaly and with spherocytes on the peripheral blood smear. The DAT is positive in most cases of immune hemolysis and negative in hereditary spherocytosis. Occasionally, the diagnosis is confused in patients with splenomegaly from other causes, especially when hypersplenism increases red cell destruction and when some spherocytes are noted on the blood smear. In such cases, the true cause of the splenomegaly may be suggested by signs or symptoms of portal hypertension or by laboratory evidence of chronic liver disease. In contrast to children with hereditary spherocytosis, those with hypersplenism typically have some degree of thrombocytopenia or neutropenia.

**Complications**

Severe jaundice may occur in the neonatal period and, if not controlled by phototherapy, may occasionally require exchange transfusion. Splenectomy is associated with an increased risk of overwhelming bacterial infections, particularly with pneumococci. Gallstones occur in 60–70% of adults who have not undergone splenectomy and may form as early as age 5–10 years.

**Treatment**

Supportive measures include the administration of folic acid to prevent the development of red cell hypoplasia due to folate deficiency. Acute exacerbations of anemia, due to increased rates of hemolysis or to aplastic crises caused by infection with human parvovirus, may be severe enough to require red cell transfusions. Splenectomy is performed in many cases and always results in significant improvement. The procedure increases the survival of the spherocytic red cells and leads to complete correction of the anemia in most cases. Patients with more severe disease may show some degree of hemolysis after splenectomy. Except in unusually severe cases, the procedure should be postponed until the child is at least age 5 years because of the greater risk of post-splenectomy sepsis prior to this age. All patients scheduled for splenectomy should be immunized with pneumococcal, *Haemophilus influenzae* type b, and meningococcal vaccines prior to the procedure, and some clinicians recommend penicillin prophylaxis afterward. Asplenic patients with fever should be promptly evaluated for severe infection. The need for splenectomy in mild cases is controversial. Splenectomy in the middle childhood years prevents the subsequent development of cholelithiasis and eliminates the need for the activity restrictions recommended for children with splenomegaly. However, these benefits must be weighed against the risks of the surgical procedure and the subsequent lifelong risk of post-splenectomy sepsis.

**Prognosis**

Splenectomy eliminates signs and symptoms in all but the most severe cases and reduces the risk of cholelithiasis. The abnormal red cell morphology and increased osmotic fragility persist without clinical consequence.

2. Hereditary Elliptocytosis

Hereditary elliptocytosis is a heterogeneous disorder that ranges in severity from an asymptomatic state with almost normal red cell morphology to severe hemolytic anemia. Most affected persons have numerous elliptocytes on the peripheral blood smear, but mild or no hemolysis. Those with hemolysis have an elevated reticulocyte count and may have jaundice and splenomegaly. These disorders are caused by mutations of red cell membrane skeletal proteins, and most have an autosomal dominant inheritance. Because most patients are asymptomatic, no treatment is indicated. Patients with significant degrees of hemolytic anemia may benefit from folate supplementation or from splenectomy.

Some infants with hereditary elliptocytosis present in the neonatal period with moderate to marked hemolysis and significant hyperbilirubinemia. This disorder has been termed transient infantile poikilocytosis because such infants exhibit bizarre erythrocyte morphology with elliptocytes, budding red cells, and small misshapen cells that defy description. The MCV is low, and the anemia may be severe enough to require red cell transfusions. Typically, one parent has hereditary elliptocytosis, usually mild or asymptomatic. The infant’s hemolysis gradually abates during the first year of life, and the erythrocyte morphology subsequently becomes more typical of hereditary elliptocytosis.

**CONGENITAL HEMOLYTIC ANEMIAS: HEMOGLOBINOPATHIES**

The hemoglobinopathies are an extremely heterogeneous group of congenital disorders that occur in many different ethnic groups. The relatively high frequency of these genetic variants is related to the malaria protection afforded to
heterozygous individuals. The hemoglobinopathies are generally classified into two major groups. The first, the thalassemias, are caused by quantitative deficiencies in the production of globin chains. These quantitative defects in globin synthesis cause microcytic and hypochromic anemias. The second group of hemoglobinopathies consists of those caused by structural abnormalities of globin chains. The most important of these, hemoglobins S, C, and E, are all the result of point mutations and single amino acid substitutions in \( \beta \)-globin. Many, but not all, infants with hemoglobinopathies are identified by routine neonatal screening.

Figure 28–3 shows the normal developmental changes that occur in globin-chain production during gestation and the first year of life. At birth, the predominant hemoglobin is fetal hemoglobin (hemoglobin F), which is composed of two \( \alpha \)-globin chains and two \( \gamma \)-globin chains. Subsequently, the production of \( \gamma \)-globin decreases and the production of \( \beta \)-globin increases so that adult hemoglobin (two \( \alpha \) chains and two \( \beta \) chains) predominates after 2–4 months. Because \( \alpha \)-globin chains are present in both fetal and adult hemoglobin, disorders of \( \alpha \)-globin synthesis (\( \alpha \)-thalassemia) are clinically manifest in the newborn as well as later in life. In contrast, patients with \( \beta \)-globin disorders such as \( \beta \)-thalassemia and sickle cell disease are generally asymptomatic during the first 3–4 months of age and present clinically after \( \gamma \)-chain production—and therefore fetal hemoglobin levels—have decreased substantially.

1. \( \alpha \)-Thalassemia

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- African, Mediterranean, Middle Eastern, Chinese, or Southeast Asian ancestry.
- Microcytic, hypochromic anemia of variable severity.
- Bart’s hemoglobin detected by neonatal screening.

**General Considerations**

Most of the \( \alpha \)-thalassemia syndromes are the result of deletions of one or more of the \( \alpha \)-globin genes on chromosome 16. Normal diploid cells have four \( \alpha \)-globin genes; thus the variable severity of the \( \alpha \)-thalassemia syndromes is related to the number of gene deletions (Table 28–1). The severity of the \( \alpha \)-thalassemia syndromes varies among affected ethnic groups, depending on the genetic abnormalities prevalent in the population. In persons of African ancestry, \( \alpha \)-thalassemia is usually caused by the deletion of only one of the two \( \alpha \)-globin genes on each chromosome. Thus, in the African population, heterozygous individuals are silent carriers and homozygous individuals have \( \alpha \)-thalassemia trait. In Asians, deletions of one or of both \( \alpha \)-globin genes on the same chromosome are common; heterozygous individuals are either silent carriers or have \( \alpha \)-thalassemia trait, and homozygous individuals or compound heterozygous individuals have \( \alpha \)-thalassemia trait, hemoglobin H disease, or hydrops fetalis. Thus, the presence of \( \alpha \)-thalassemia in a child of Asian ancestry may have important implications for genetic counseling, whereas this is not usually the case in families of African ancestry.

**Clinical Findings**

The clinical findings depend on the number of \( \alpha \)-globin genes deleted. Table 28–1 summarizes the \( \alpha \)-thalassemia syndromes.

Persons with three \( \alpha \)-globin genes (one-gene deletion) are asymptomatic and have no hematologic abnormalities. Hemoglobin levels and MCV are normal. Hemoglobin electrophoresis in the neonatal period shows 0–3% Bart’s hemoglobin, which is a variant hemoglobin composed of four \( \gamma \)-globin chains. Hemoglobin electrophoresis after the first few months of life is normal. Thus, this condition is usually suspected only in the context of family studies or when a small amount of Bart’s hemoglobin is detected by neonatal screening for hemoglobinopathies.

*α indicates presence of α-globin gene, – indicates deletion of α-globin gene.
*N = normal results, Hb = hemoglobin, Hb Bart’s = γα, Hb H = βα.

Persons with two α-globin genes (two-gene deletion) are typically asymptomatic. The MCV is usually less than 100 fL at birth. Hematologic studies in older infants and children show a normal or slightly decreased hemoglobin level with a low MCV and a slightly hypochromic blood smear with some target cells. The hemoglobin electrophoresis typically shows 2–10% Bart’s hemoglobin in the neonatal period but is normal in older children and adults.

Persons with one α-globin gene (three-gene deletion) have a mild to moderately severe microcytic hemolytic anemia (hemoglobin level of 7–10 g/dL), which may be accompanied by hepatosplenomegaly and some bony abnormalities caused by the expanded medullary space. The reticulocyte count is elevated, and the red cells show marked hypochromia and microcytosis with significant poikilocytosis and some basophilic stippling. Hemoglobin electrophoresis in the neonatal period typically shows 15–30% Bart’s hemoglobin. Later in life, hemoglobin H (composed of four β-globin chains) is present. Incubation of red cells with brilliant cresyl blue (hemoglobin H preparation) shows inclusion bodies formed by denatured hemoglobin H.

The deletion of all four α-globin genes causes severe intrauterine anemia and asphyxia and results in hydrops fetalis and fetal demise or neonatal death shortly after delivery. Extreme pallor and massive hepatosplenomegaly are present. Hemoglobin electrophoresis reveals a predominance of Bart’s hemoglobin with a complete absence of normal fetal or adult hemoglobin.

**Differential Diagnosis**

α-Thalassemia trait (two-gene deletion) must be differentiated from other mild microcytic anemias, including iron deficiency and β-thalassemia minor (see next section). In contrast to children with iron deficiency, children with α-thalassemia trait show normal or increased levels of ferritin and serum iron. In contrast to children with β-thalassemia minor, children with α-thalassemia trait have a normal hemoglobin electrophoresis after age 4–6 months. Finally, the history of a low MCV (96 fL) at birth or the presence of Bart’s hemoglobin on the neonatal hemoglobinopathy screening test suggests α-thalassemia.

Children with hemoglobin H disease may have jaundice and splenomegaly, and the disorder must be differentiated from other hemolytic anemias. The key to the diagnosis is the decreased MCV and the marked hypochromia on the blood smear. With the exception of β-thalassemia, most other significant hemolytic disorders have a normal or elevated MCV and the red blood cells are not hypochromic. Infants with hydrops fetalis due to severe α-thalassemia must be distinguished from those with hydrops due to other causes of anemia, such as alloimmunization.

**Complications**

The principal complication of α-thalassemia trait is the needless administration of iron, given in the belief that a mild microcytic anemia is due to iron deficiency. Persons with hemoglobin H disease may have intermittent exacerbations of their anemia in response to oxidant stress or infection, which occasionally require blood transfusions. Splenomegaly may exacerbate the anemia and may require splenectomy. Women pregnant with hydropic α-thalassemia fetuses are subject to increased complications of pregnancy, particularly toxemia and postpartum hemorrhage.

**Treatment**

Persons with α-thalassemia trait require no treatment. Those with hemoglobin H disease should receive supplemental folic acid and avoid the same oxidant drugs that cause hemolysis in persons with G6PD deficiency, because exposure to these drugs may exacerbate their anemia. The anemia may also be exacerbated during periods of infection, and transfusions may be required. Hypersplenism may develop later in childhood and require surgical splenectomy. Genetic counseling and prenatal diagnosis should be offered to families at risk for hydropic fetuses.

2. β-Thalassemia

**β-Thalassemia minor:**

- Normal neonatal screening test.
- African, Mediterranean, Middle Eastern, or Asian ancestry.
► Mild microcytic, hypochromic anemia.
► No response to iron therapy.
► Elevated level of hemoglobin A₂.

β-Thalassemia major:
► Neonatal screening shows hemoglobin F only.
► Mediterranean, Middle Eastern, or Asian ancestry.
► Severe microcytic, hypochromic anemia with marked hepatosplenomegaly.

General Considerations
In contrast to the four α-globin genes, only two β-globin genes are present in diploid cells, one on each chromosome 11. Some β-thalassemia genes produce no β-globin chains and are termed β₀-thalassemia. Other β-globin genes produce some β-globin, but in diminished quantities, and are termed β⁺-thalassemia. Persons affected by β-thalassemia may be heterozygous or homozygous. Individuals heterozygous for most β-thalassemia genes have β-thalassemia minor. Homozygous individuals have β-thalassemia major (Cooley anemia), a severe transfusion-dependent anemia, or a condition known as thalassemia intermedia, which is more severe than thalassemia minor but is not generally transfusion-dependent. β-Thalassemia major is the most common worldwide cause of transfusion-dependent anemia in childhood. In addition, β-thalassemia genes interact with genes for structural β-globin variants such as hemoglobin S and hemoglobin E to cause serious disease in compound heterozygous individuals. These disorders are discussed further in the sections dealing with sickle cell disease and with hemoglobin E disorders.

Clinical Findings
A. Symptoms and Signs
Persons with β-thalassemia minor are usually asymptomatic with a normal physical examination. Those with β-thalassemia major are normal at birth but develop significant anemia during the first year of life. If the disorder is not identified and treated with blood transfusions, such children grow poorly and develop massive hepatosplenomegaly and enlargement of the medullary space with thinning of the bony cortex. The skeletal changes cause characteristic facial deformities (prominent forehead and maxilla) and predispose the child to pathologic fractures.

B. Laboratory Findings
Children with β-thalassemia minor have normal neonatal screening results but subsequently develop a decreased MCV with or without mild anemia. The peripheral blood smear typically shows hypochromia, target cells, and sometimes basophilic stippling. Hemoglobin electrophoresis performed after 6–12 months of age is usually diagnostic when levels of hemoglobin A₂, hemoglobin F, or both are elevated. β-Thalassemia major is often initially suspected when hemoglobin A is absent on neonatal screening. Such infants are hematologically normal at birth, but develop severe anemia after the first few months of life. The peripheral blood smear typically shows a severe hypochromic, microcytic anemia with marked anisocytosis and poikilocytosis. Target cells are prominent, and nucleated red blood cells often exceed the number of circulating white blood cells. The hemoglobin level usually falls to 5–6 g/dL or less, and the reticulocyte count is elevated, but the reticulocyte index is normal to decreased. Platelet and white blood cell counts may be increased, and the serum bilirubin level is elevated. The bone marrow shows marked erythroid hyperplasia, but this finding is rarely needed for diagnosis. Hemoglobin electrophoresis shows only fetal hemoglobin and hemoglobin A₂ in children with homozygous β-thalassemia.

Those with β⁺-thalassemia genes make some hemoglobin A but have a marked increase in fetal hemoglobin and hemoglobin A₂ levels. The diagnosis of homozygous β-thalassemia may also be suggested by the finding of β-thalassemia minor in both parents.

Differential Diagnosis
β-Thalassemia minor must be differentiated from other causes of mild microcytic, hypochromic anemias, principally iron deficiency and α-thalassemia. In contrast to patients with iron-deficiency anemia, those with β-thalassemia minor typically have an elevated number of red blood cells, and the index of the MCV divided by the red cell count is under 13. Generally, the finding of an elevated hemoglobin A₂ level is diagnostic; however, the A₂ level is lowered by coexistent iron deficiency. Thus, in children thought to be iron-deficient, hemoglobin electrophoresis with quantitation of hemoglobin A₂ is sometimes deferred until after a course of iron therapy.

β-Thalassemia major is rarely confused with other disorders. Hemoglobin electrophoresis and family studies readily distinguish it from hemoglobin E/β-thalassemia, which is the other important cause of transfusion-dependent thalassemia.

Complications
The principal complication of β-thalassemia minor is the unnecessary use of iron therapy in a futile attempt to correct the microcytic anemia. Children with β-thalassemia major who are inadequately transfused experience poor growth and recurrent infections and may have hepatosplenomegaly, thinning of the cortical bone, and pathologic fractures. Without treatment, most children die within the first decade of life. The principal complications of β-thalassemia major in transfused children are hemosiderosis, splenomegaly, and hypersplenism. Transfusion-related hemosiderosis requires chelation therapy with deferoxamine, given parentally, or deferasirox (Exjade),...
given orally, to prevent cardiac, hepatic, and endocrine dysfunction. Noncompliance with chelation in adolescents and young adults may lead to death from congestive heart failure, cardiac arrhythmias, or hepatic failure. Even with adequate transfusions, many patients develop splenomegaly and some degree of hypersplenism. This may require surgical splenectomy because of the increasing transfusion requirements, but the procedure increases the risk of thrombosis and overwhelming septicemia.

**Treatment**

β-Thalassemia minor requires no specific therapy, but diagnosis of the condition may have important genetic implications for the family. For patients with β-thalassemia major, two treatments are available: chronic transfusion with iron chelation and stem cell transplantation. Programs of blood transfusion are generally targeted to maintain a nadir hemoglobin level of 9–10 g/dL. This approach gives increased vigor and well-being, improved growth, and fewer overall complications. However, maintenance of good health currently requires iron chelation. Small doses of supplemental ascorbic acid may enhance the efficacy of iron chelation. Patients who undergo splenectomy to reduce transfusion requirements, and hence iron loading, should receive pneumococcal vaccine prior to the procedure and prophylactic penicillin and urgent treatment of all febrile illness after splenectomy.

Bone marrow or umbilical cord blood transplantation is an important therapeutic option for children with β-thalassemia major who have an HLA-identical sibling donor. The probability of hematologic cure is greater than 90% when transplantation is performed prior to the development of hepatomegaly or portal fibrosis.

3. Sickle Cell Disease

**General Considerations**

A high prevalence of sickle hemoglobin is found in persons of central African origin. It also occurs in other ethnic groups in Italy, Greece, Turkey, Saudi Arabia, and India. Sickle cell anemia is caused by homozygosity for the sickle gene and is the most common form of sickle cell disease. Other clinically important sickling disorders are compound heterozygous conditions in which the sickle gene interacts with genes for hemoglobins C, D_Punjab, O_Arab, C_Harlem, or β-thalassemia.

Overall, sickle cell disease occurs in about 1 of every 400 African American infants. Eight percent of African Americans are heterozygous carriers of the sickle gene and are said to have sickle cell trait.

The protean clinical manifestations of sickle hemoglobinopathies can be linked directly or indirectly to the propensity of deoxygenated hemoglobin S to polymerize. Polymerization of sickle hemoglobin distorts erythrocyte morphology, decreases red cell deformability, causes a marked reduction in red cell life span, increases blood viscosity, and predisposes to episodes of vaso-occlusion.

Neonatal screening for sickle hemoglobinopathies is now routine in most of the United States. The identification of affected infants at birth, when combined with follow-up programs of parental education, comprehensive medical care, and prophylactic penicillin, markedly reduces morbidity and mortality in early childhood.

**Clinical Findings**

A. Symptoms and Signs

These are related to the hemolytic anemia and to tissue ischemia and organ dysfunction caused by vaso-occlusion. Physical findings are normal at birth, and symptoms are unusual before age 3–4 months because high levels of fetal hemoglobin inhibit sickling. A moderately severe hemolytic anemia may be present by age 1 year. This causes pallor, fatigue, and jaundice, and predisposes to the development of gallstones during childhood and adolescence. Intense congestion of the spleen with sickled cells may cause splenomegaly in early childhood and results in functional asplenia as early as age 3 months. This places children at great risk for overwhelming infection with encapsulated bacteria, particularly pneumococci. Up to 30% of patients experience one or more episodes of acute splenic sequestration, characterized by sudden enlargement of the spleen with pooling of red cells, acute exacerbation of anemia, and, in severe cases, shock and death. Acute exacerbation of anemia also occurs with aplastic crises, usually caused by infection with human parvovirus, and other viruses.

Recurrent episodes of vaso-occlusion and tissue ischemia cause acute and chronic problems. Dactylitis, or hand-and-foot syndrome, is the most common initial symptom of the disease and occurs in up to 50% of children before age 3 years. Recurrent episodes of abdominal and musculoskeletal pain may occur throughout life. Strokes occur in about 8%
of children and tend to be recurrent. The so-called acute chest syndrome, characterized by fever, pleuritic chest pain, and acute pulmonary infiltrates with hypoxemia, is caused by pulmonary infection, infarction, or fat embolism from ischemic bone marrow. All tissues are susceptible to damage from vaso-occlusion, and multiple organ dysfunction is common by adulthood. Table 28–2 lists the common manifestations of sickle cell disease in children and adults.

### B. Laboratory Findings

Children with sickle cell anemia (homozygous sickle cell disease) generally show a baseline hemoglobin level of 7–10 g/dL. This value may fall to life-threatening levels at the time of a sequestration or aplastic crisis. The baseline reticulocyte count is elevated markedly. The anemia is usually normocytic or macrocytic, and the peripheral blood smear typically shows the characteristic sickle cells as well as numerous target cells. Patients with sickle β-thalassemia also generally have a low MCV and hypochromia. Those with sickle β-thalassemia tend to have less hemolysis and anemia. Persons with sickle hemoglobin C disease have fewer sickle forms and more target cells, and the hemoglobin level may be normal or only slightly decreased because the rate of hemolysis is much less than in sickle cell anemia.

Most infants with sickle hemoglobinopathies born in the United States are identified by neonatal screening. Results indicative of possible sickle cell disease require prompt confirmation with hemoglobin electrophoresis. Children with sickle cell anemia and with sickle β-thalassemia have only hemoglobins S and F. Persons with sickle β-thalassemia have a preponderance of hemoglobin S with a lesser amount of hemoglobin A. Persons with sickle hemoglobin C disease have equal amounts of hemoglobins S and C. The use of solubility tests to screen for the presence of sickle hemoglobin should be avoided because a negative result is frequently encountered in infants with sickle cell disease, and because a positive result in an older child does not differentiate sickle cell trait from sickle cell disease. Thus, hemoglobin electrophoresis is always necessary to accurately identify a sickle disorder.

#### Differential Diagnosis

Hemoglobin electrophoresis and sometimes hematologic studies of the parents are usually sufficient to confirm the correct diagnosis of a sickle cell disorder. Infants whose neonatal screening test shows only hemoglobins F and S occasionally have disorders other than sickle cell anemia or sickle β-thalassemia. The most important of these disorders is a compound heterozygous condition of sickle hemoglobin and pancellular hereditary persistence of fetal hemoglobin. Such children, when older, typically have 30% fetal hemoglobin and 70% hemoglobin S, but they do not have significant anemia or develop vaso-occlusive episodes.

#### Complications

Repeated tissue ischemia and infarction causes damage to virtually every organ system. Table 28–2 lists the most important complications. Patients who require multiple transfusions are at risk of developing transfusion-related hemosiderosis and red cell alloantibodies.

#### Treatment

The cornerstone of treatment is enrollment in a program involving patient and family education, comprehensive outpatient care, and appropriate treatment of acute complications. Important to the success of such a program are psychosocial services, blood bank services, and the ready availability of baseline patient information in the setting in which acute illnesses are evaluated and treated. Management of sickle cell anemia and sickle β-thalassemia includes prophylactic penicillin, which should be initiated by age 2 months and continued at least until age 5 years.

The routine use of penicillin prophylaxis in sickle hemoglobin C disease and sickle β-thalassemia is controversial. Pneumococcal conjugate and polysaccharide vaccine should be administered to all children who have sickle cell disease. Other routine immunizations, including yearly vaccination against influenza, should be provided. All illnesses associated with fever greater than 38.5°C should be evaluated promptly, bacterial cultures performed, parenteral broad-spectrum antibiotics administered, and careful inpatient or outpatient observation conducted.
Treatment of painful vaso-occlusive episodes includes the maintenance of adequate hydration (with avoidance of overhydration), correction of acidosis if present, administration of adequate analgesia, maintenance of normal oxygen saturation, and the treatment of any associated infections.

Red cell transfusions play an important role in management. Transfusions are indicated to improve oxygen-carrying capacity during acute severe exacerbations of anemia, as occurs during episodes of splenic sequestration or aplastic crisis. Red cell transfusions are not indicated for the treatment of chronic steady-state anemia, which is usually well tolerated, or for uncomplicated episodes of vaso-occlusive pain. Simple or partial exchange transfusion to reduce the percentage of circulating sickle cells is indicated for some severe acute vaso-occlusive events and may be lifesaving. These events include stroke, moderate to severe acute chest syndrome, and acute life-threatening failure of other organs. Transfusions may also be used prior to high-risk procedures such as surgery with general anesthesia and arteriograms with ionic contrast materials. Some patients who develop severe vaso-occlusive complications may benefit from chronic transfusion therapy. The most common indication for transfusion is stroke. Without transfusions, children with stroke have a 70–80% chance of recurrent stroke within a 2-year period. This risk of recurrent neurologic events is reduced markedly by the transfusion therapy.

Successful stem cell transplantation cures sickle cell disease, but to date its use has been limited because of the risks associated with the procedure, the inability to predict in young children the severity of future complications, and the paucity of HLA-identical sibling donors. Daily administration of oral hydroxyurea increases levels of fetal hemoglobin, decreases hemolysis, and reduces by 50% episodes of pain in severely affected adults with sickle cell anemia. The hematologic effects and short-term toxicity of hydroxyurea in children are similar to those in adults. Thus hydroxyurea is being used increasingly for selected children and adolescents who have frequent, severe complications.

### Prognosis

Early identification by neonatal screening of infants with sickle cell disease, combined with comprehensive care that includes prophylactic penicillin, has markedly reduced mortality in childhood. Most patients now live well into adulthood, but eventually succumb to complications.

Individuals who are heterozygous for the sickle gene are said to have sickle cell trait. This genetic carrier state occurs in 8% of African Americans and is more common in some areas of Africa and the Middle East. Infants with sickle cell trait are identified by neonatal screening results that show hemoglobin FAS. Accurate identification of older persons with sickle cell trait depends on hemoglobin electrophoresis, which typically shows about 60% hemoglobin A and about 40% hemoglobin S. No anemia or hemolysis is present, and the physical examination is normal. Persons with sickle cell trait are generally healthy, and experience no illness attributable to the presence of sickle hemoglobin in their red cells. Life expectancy is normal.

Sickle trait erythrocytes are capable of sickling, particularly under conditions of significant hypoxemia, and several clinical abnormalities have been linked to this genetic carrier state. Exposure to environmental hypoxia (altitude > 3100 m [10,000 ft] above sea level) may precipitate splenic infarction. However, most persons with sickle cell trait who choose to visit such altitudes for skiing, hiking, or climbing do so without difficulty. Many develop some degree of hyposthenuria, and about 4% experience painless hematuria, usually microscopic but occasionally macroscopic. For the most part, these renal abnormalities are subclinical and do not progress to significant renal dysfunction. The incidence of bacteriuria and pyelonephritis may be increased during pregnancy, but overall rates of maternal and infant morbidity and mortality are not affected by the presence of sickle cell trait in the pregnant woman.

An epidemiologic study of army recruits in military basic training found a higher risk of sudden unexplained death following strenuous exertion in recruits with sickle cell trait than in those with normal hemoglobin. This study has raised concerns about exercise and exertion for persons with the trait. However, considerable evidence suggests that exercise is generally safe and that athletic performance is not adversely affected by sickle cell trait. Exercise tolerance is normal, and the incidence of sickle cell trait in black professional football players is similar to that of the general African-American population, suggesting no barrier to achievement in such a physically demanding profession. Thus, restrictions on athletic competition for children with sickle cell trait are not warranted. Sickle cell trait is most significant for its genetic implications.

### 5. Hemoglobin C Disorders

Hemoglobin C is detected by neonatal screening. Two percent of African Americans are heterozygous for hemoglobin C and are said to have hemoglobin C trait. Such individuals have no symptoms, anemia, or hemolysis, but the peripheral blood smear may show some target cells. Identification of persons with hemoglobin C trait is important for genetic counseling, particularly with regard to the possibility of sickle hemoglobin C disease in offspring.
Persons with homozygous hemoglobin C have a mild microcytic hemolytic anemia and may develop splenomegaly. The peripheral blood smear shows prominent target cells. As with other hemolytic anemias, complications of homozygous hemoglobin C include gallstones and aplastic crises.

6. Hemoglobin E Disorders

Hemoglobin E is the second most common hemoglobin variant worldwide, with a gene frequency greater than 10% in some areas of Thailand and Cambodia. In Southeast Asia, an estimated 30 million people have hemoglobin E trait. Persons heterozygous for hemoglobin E show hemoglobin FAE by neonatal screening and are asymptomatic or usually not anemic, but they may develop mild microcytosis. Persons homozygous for hemoglobin E are also asymptomatic but may have mild anemia; the peripheral blood smear shows microcytosis and some target cells.

Hemoglobin E is most important because of its interaction with β-thalassemia. Compound heterozygotes for hemoglobin E and β-thalassemia are normal at birth and, like infants with homozygous E, show hemoglobin FE on neonatal screening. Unlike homozygotes, they subsequently develop mild to severe microcytic hypochromic anemia. Such children may exhibit jaundice, hepatosplenomegaly, and poor growth if the disorder is not recognized and treated appropriately. In some cases, the anemia becomes severe enough to require lifelong transfusion therapy. In certain areas of the United States, hemoglobin E/β-thalassemia has become a more common cause of transfusion-dependent anemia than homozygous β-thalassemia.

7. Other Hemoglobinopathies

Hundreds of other human globin-chain variants have been described. Some, such as hemoglobins D and G, are relatively common. Heterozygous individuals, who are frequently identified during the course of neonatal screening programs for hemoglobinopathies, are generally asymptomatic and usually have no anemia or hemolysis. The principal significance of most hemoglobin variants is the potential for disease in compound heterozygous individuals who also inherit a gene for β-thalassemia or sickle hemoglobin. For example, children who are compound heterozygous for hemoglobins S and D_Punjab (D_Los Angeles) have sickle cell disease.

CONGENITAL HEMOLYTIC ANEMIAS: DISORDERS OF RED CELL METABOLISM

Erythrocytes depend on the anaerobic metabolism of glucose for the maintenance of adenosine triphosphate levels sufficient for homeostasis. Glycolysis also produces the 2,3-diphosphoglycerate levels needed to modulate the oxygen affinity of hemoglobin. Glucose metabolism via the hexose monophosphate shunt is necessary to generate sufficient reduced nicotinamide adenine dinucleotide phosphate (NADH) and reduced glutathione to protect red cells against oxidant damage. Congenital deficiencies of many glycolytic pathway enzymes have been associated with hemolytic anemias. In general, the morphologic abnormalities present on the peripheral blood smear are nonspecific, and the inheritance of these disorders is autosomal recessive or X-linked. Thus, the possibility of a red cell enzyme defect should be considered during the evaluation of a patient with a congenital hemolytic anemia in the following instances: when the peripheral blood smear does not show red cell morphology typical of membrane or hemoglobin defects (eg, spherocytes, sickle forms, target cells); when hemoglobin disorders are excluded by hemoglobin electrophoresis and by isopropanol precipitation tests; and when family studies do not suggest an autosomal dominant disorder. The diagnosis is confirmed by finding a low level of the deficient enzyme.

The two most common disorders of erythrocyte metabolism are G6PD deficiency and pyruvate kinase deficiency.

1. Glucose-6-Phosphate Dehydrogenase (G6PD) Deficiency

African, Mediterranean, or Asian ancestry.

Neonatal hyperbilirubinemia.

Sporadic hemolysis associated with infection or with ingestion of oxidant drugs or fava beans.

X-linked inheritance.

General Considerations

Deficiency of G6PD is the most common red cell enzyme defect that causes hemolytic anemia. The disorder has X-linked recessive inheritance and occurs with high frequency among persons of African, Mediterranean, and Asian ancestry. Hundreds of different G6PD variants have been characterized. In most instances, the deficiency is due to enzyme instability; thus, older red cells are more deficient than younger ones, and are unable to generate sufficient NADH to maintain the levels of reduced glutathione necessary to protect the red cells against oxidant stress. Thus, most persons with G6PD deficiency do not have a chronic hemolytic anemia; instead, they have episodic hemolysis at times of exposure to the oxidant stress of infection or of certain drugs or food substances. The severity of the disorder varies among ethnic groups; G6PD deficiency in persons of African ancestry usually is less severe than in other ethnic groups.
Clinical Findings

A. Symptoms and Signs

Infants with G6PD deficiency may have significant hyperbilirubinemia and require phototherapy or exchange transfusion to prevent kernicterus. The deficiency is an important cause of neonatal hyperbilirubinemia in infants of Mediterranean or Asian ancestry, but less so in infants of African ancestry. Older children with G6PD deficiency are asymptomatic and appear normal between episodes of hemolysis. Hemolytic episodes are often triggered by infection or by the ingestion of oxidant drugs such as antimalarial compounds and sulfonamide antibiotics (Table 28–3). Ingestion of fava beans may trigger hemolysis in children of Mediterranean or Asian ancestry but usually not in children of African ancestry. Episodes of hemolysis are associated with pallor, jaundice, hemoglobinuria, and sometimes cardiovascular compromise.

B. Laboratory Findings

The hemoglobin concentration, reticulocyte count, and peripheral blood smear are usually normal in the absence of oxidant stress. Episodes of hemolysis are associated with a variable fall in hemoglobin. “Bite” cells or blister cells may be seen, along with a few spherocytes. Hemoglobinuria is common, and the reticulocyte count increases within a few days. Heinz bodies may be demonstrated with appropriate stains. The diagnosis is confirmed by the finding of reduced levels of G6PD in erythrocytes. Because this enzyme is present in increased quantities in reticulocytes, the test is best performed at a time when the reticulocyte count is normal or near normal.

Complications

Kernicterus is a risk for infants with significant neonatal hyperbilirubinemia. Episodes of acute hemolysis in older children may be life-threatening. Rare G6PD variants are associated with chronic hemolytic anemia; the clinical course of patients with such variants may be complicated by splenomegaly and by the formation of gallstones.

Treatment

The most important treatment issue is avoidance of drugs known to be associated with hemolysis (see Table 28–3). For some patients of Mediterranean, Middle Eastern, or Asian ancestry, the consumption of fava beans must also be avoided. Infections should be treated promptly and antibiotics given when appropriate. Most episodes of hemolysis are self-limiting, but red cell transfusions may be lifesaving when signs and symptoms indicate cardiovascular compromise.

2. Pyruvate Kinase Deficiency

Pyruvate kinase deficiency is an autosomal recessive disorder observed in all ethnic groups but is most common in northern Europeans. The deficiency is associated with a chronic hemolytic anemia of varying severity. Approximately one third of those affected present in the neonatal period with jaundice and hemolysis that require phototherapy or exchange transfusion. Occasionally, the disorder causes hydrops fetalis and neonatal death. In older children, the hemolysis may require red cell transfusions or be mild enough to go unnoticed for many years. Jaundice and splenomegaly frequently occur in the more severe cases. The diagnosis of pyruvate kinase deficiency is occasionally suggested by the presence of echinocytes on the peripheral blood smear, but these findings may be absent prior to splenectomy. The diagnosis depends on the demonstration of low levels of pyruvate kinase activity in red cells.

Treatment of pyruvate kinase depends on the severity of the hemolysis. Blood transfusions may be required for significant anemia, and splenectomy may be beneficial. Although the procedure does not cure the disorder, it ameliorates the anemia and its symptoms. Characteristically, the reticulocyte count increases and echinocytes become more prevalent after splenectomy, despite the decreased hemolysis and increased hemoglobin level.

ACQUIRED HEMOLYTIC ANEMIA

1. Autoimmune Hemolytic Anemia

Essentials of Diagnosis & Typical Features

- Pallor, fatigue, jaundice, and dark urine.
- Splenomegaly.
- Positive DAT.
- Reticulocytosis and spherocytosis.

General Considerations

Acquired autoimmune hemolytic anemia is rare during the first 4 months of life but is one of the more common causes of acute anemia after the first year. It may arise as an isolated problem or may complicate an infection (hepatitis, upper respiratory tract infections, mononucleosis, or cytomegalovirus infection); systemic lupus erythematosus and other autoimmune syndromes;
immunodeficiency states, including autoimmune lymphoproliferative syndrome; or, rarely, malignancies.

**Clinical Findings**

**A. Symptoms and Signs**

The disease usually has an acute onset manifested by weakness, pallor, dark urine, and fatigue. Jaundice is a prominent finding, and splenomegaly is often present. Some cases have a more chronic, insidious onset. Clinical evidence of an underlying disease may be present.

**B. Laboratory Findings**

The anemia is normochromic and normocytic and may vary from mild to severe (hemoglobin concentration < 5 g/dL). The reticulocyte count and index are usually increased but occasionally are normal or low. Spherocytes and nucleated red cells may be seen on the peripheral blood smear. Although leukocytosis and elevated platelet counts are a common finding, thrombocytopenia occasionally occurs. Other laboratory data consistent with hemolysis are present, such as increased indirect and total bilirubin, lactic dehydrogenase, aspartate aminotransferase, and urinary urobilinogen. Intravascular hemolysis is indicated by hemoglobinemia or hemoglobinuria. Examination of bone marrow shows marked erythroid hyperplasia and hemophagocytosis, but is seldom required for the diagnosis.

Serologic studies are helpful in defining pathophysiology, planning therapeutic strategies, and assessing prognosis (Table 28–4). In almost all cases, the direct and indirect antiglobulin (DAT and IAT) tests are positive. Further evaluation allows distinction into one of three syndromes. The presence of IgG on the patient’s red blood cells, maximal in-vitro antibody activity at 37°C, and either no antigen specificity or an Rh-like specificity constitute warm autoimmune hemolytic anemia with extravascular destruction by the reticuloendothelial system. In contrast, the detection of complement alone on red blood cells, optimal reactivity in vitro at 4°C, and I or i antigen specificity are diagnostic of cold autoimmune hemolytic anemia with intravascular hemolysis. Although cold agglutinins are relatively common (~10%) in normal individuals, clinically significant cold antibodies exhibit in-vitro reactivity at 30°C or above.

Paroxysmal cold hemoglobinuria usually has a different cause. The laboratory evaluation is identical to cold autoimmune hemolytic anemia except for antigen specificity (P) and the exhibition of in-vitro hemolysis. Paroxysmal cold hemoglobinuria is almost always associated with significant infections, such as *Mycoplasma*, Epstein-Barr virus (EBV), and cytomegalovirus (CMV). Warm IgM antibodies are rare.

**Differential Diagnosis**

Autoimmune hemolytic anemia must be differentiated from other forms of congenital or acquired hemolytic anemias. The DAT discriminates antibody-mediated hemolysis from other causes, such as hereditary spherocytosis. The presence of other cytopenias and antibodies to platelets or neutrophils suggests Evans syndrome.

IVIG, intravenous immune globulin; RES, reticuloendothelial system.
Complications

The anemia may be very severe and result in cardiovascular collapse, requiring emergency management. The complications of an underlying disease, such as disseminated lupus erythematosus or an immunodeficiency state, may be present.

Treatment

Medical management of the underlying disease is important in symptomatic cases. Defining the clinical syndrome provides a useful guide to treatment. Most patients with warm autoimmune hemolytic anemia (in which hemolysis is mostly extravascular) respond to prednisone (2–4 mg/kg/d). After the initial treatment, the dose of corticosteroids may be decreased slowly. Patients may respond to 1 g of intravenous immune globulin (IVIG) per kilogram per day for 2 days, but fewer patients respond to IVIG than to prednisone. Although the rate of remission with splenectomy may be as high as 50%, particularly in warm autoimmune hemolytic anemia, this should be carefully considered in younger patients and withheld until other treatments have failed. In severe cases unresponsive to more conventional therapy, immunosuppressive agents such as cyclophosphamide, azathioprine, busulfan, and cyclosporine may be tried alone or in combination with corticosteroids. In refractory cases, rituximab may be a successful alternative, and transplantation has been used in a small number of cases.

Patients with cold autoimmune hemolytic anemia and paroxysmal cold hemoglobinuria are less likely to respond to corticosteroids or IVIG. Because these syndromes are most apt to be associated with infections and have an acute, self-limited course, supportive care may be sufficient. Plasma exchange may be effective in severe cold autoimmune (IgM) hemolytic anemia because the offending antibody has an intravascular distribution.

Supportive therapy is crucial. Patients with cold-reacting antibodies, particularly paroxysmal cold hemoglobinuria, should be kept in a warm environment. Transfusion may be necessary because of the complications of severe anemia but should be used only when there is no alternative. In most patients, cross-match compatible blood will not be found, and the least incompatible unit should be identified. Transfusion must be conducted carefully, beginning with a test dose (see Transfusion Medicine section, later in this chapter). Identification of the patient’s phenotype for minor red cell alloantigens may be helpful in avoiding alloimmunization or in providing appropriate transfusions if alloantibodies arise after initial transfusions. Patients with severe intravascular hemolysis may have associated disseminated intravascular coagulation (DIC), and heparin therapy should be considered in such cases.

Prognosis

The outlook for autoimmune hemolytic anemia in childhood usually is good unless associated diseases are present (eg, congenital immunodeficiency, AIDS, lupus erythematosus), in which case hemolysis is likely to have a chronic course. In general, children with warm autoimmune hemolytic anemia are at greater risk for more severe and chronic disease with higher morbidity and mortality rates. Hemolysis and positive antiglobulin tests may continue for months or years. Patients with cold autoimmune hemolytic anemia or paroxysmal cold hemoglobinuria are more likely to have acute, self-limited disease (< 3 months). Paroxysmal cold hemoglobinuria is almost always associated with infection (eg, Mycoplasma infection, CMV, and EBV).

2. Nonimmune Acquired Hemolytic Anemia

Hepatic disease may alter the lipid composition of the red cell membrane. This usually results in the formation of target cells and is not associated with significant hemolysis.

Occasionally, hepatocellular damage is associated with the formation of spur cells and brisk hemolytic anemia. Renal disease may also be associated with significant hemolysis; hemolytic-uremic syndrome is one example. In this disorder, hemolysis is associated with the presence, on the peripheral blood smear, of echinocytes, helmet cells, fragmented red cells, and spherocytes.

A microangiopathic hemolytic anemia with fragmented red cells and some spherocytes may be observed in several conditions associated with intravascular coagulation and fibrin deposition within vessels. This occurs with DIC such as may complicate severe infection, but it may also occur when the intravascular coagulation is localized, as with giant cavernous hemangiomas (Kasabach-Merritt syndrome). Fragmented red cells may also be seen with mechanical damage (eg, associated with artificial heart valves).

POLYCYTHEMIA & METHEMOGLOBINEMIA

CONGENITAL ERYTHROCYTOSIS (FAMILIAL POLYCYTHEMIA)

In pediatrics, polycythemia is usually secondary to chronic hypoxemia. However, several families with congenital erythrocytosis have been described. The disorder differs from polycythemia vera in that only red blood cells are affected; the
white blood cell and platelet counts are normal. It occurs as an autosomal dominant or recessive disorder. There are usually no physical findings except for plethora and splenomegaly. The hemoglobin level may be as high as 27 g/dL. Patients usually have no symptoms other than headache and lethargy. Studies in a number of families have revealed (1) abnormal hemoglobin with altered oxygen affinity, (2) reduced red cell diphosphoglycerate, (3) autonomous increase in erythropoietin production, or (4) hypersensitivity of erythroid precursors to erythropoietin.

Treatment is not indicated unless symptoms are marked. Phlebotomy is the treatment of choice.

SECONDARY POLYCYTHEMIA

Secondary polycythemia occurs in response to hypoxemia. The most common cause of secondary polycythemia in children is cyanotic congenital heart disease. It also occurs in chronic pulmonary disease such as cystic fibrosis. Persons living at extremely high altitudes, as well as some with methemoglobinemia, develop polycythemia. It has on rare occasions been described without hypoxemia in association with renal tumors, brain tumors, Cushing disease, or hydrolephrosis.

Polycythemia may occur in the neonatal period; it is particularly exaggerated in infants who are preterm or small for gestational age. In these infants, polycythemia is sometimes associated with other symptoms. It may occur in infants of diabetic mothers, in Down syndrome, and as a complication of congenital adrenal hyperplasia.

Iron deficiency may complicate polycythemia and aggravate the associated hyperviscosity. This complication should always be suspected when the MCV falls below the normal range. Coagulation and bleeding abnormalities, including thrombocytopenia, mild consumption coagulopathy, and elevated fibrinolytic activity, have been described in severely polycythemic cardiac patients. Bleeding at surgery may be severe.

The ideal treatment of secondary polycythemia is correction of the underlying disorder. When this cannot be done, phlebotomy may be necessary to control symptoms. Iron sufficiency should be maintained. Adequate hydration of the patient and phlebotomy with plasma replacement may be indicated prior to major surgical procedures. These measures prevent the complications of thrombosis and hemorrhage. Isovolumetric exchange transfusion is the treatment of choice in severe cases.

METHEMOGLOBINEMIA

Methemoglobin is continuously formed at a slow rate by the oxidation of heme iron to the ferric state. Normally, it is enzymatically reduced back to hemoglobin. Methemoglobin is unable to transport oxygen and causes a shift in the dissociation curve of the residual oxyhemoglobin. Cyanosis is produced with methemoglobin levels of approximately 15% or greater. Levels of methemoglobin increase by several mechanisms.

1. Hemoglobin M

The designation M is given to several abnormal hemoglobins associated with methemoglobinemia. Affected individuals are heterozygous for the gene, which is transmitted as an autosomal dominant disorder. The different types of hemoglobin M result from different amino acid substitutions in α- or β-globin. Hemoglobin electrophoresis at the usual pH will not always demonstrate the abnormal hemoglobin, and isoelectric focusing may be needed. The patient has cyanosis but is otherwise usually asymptomatic. Exercise tolerance may be normal, and life expectancy is not affected. This type of methemoglobinemia does not respond to any form of therapy.

2. Congenital Methemoglobinemia Due to Enzyme Deficiencies

Congenital methemoglobinemia is caused most frequently by congenital deficiency of the reducing enzyme diaphorase I (coenzyme factor I). It is transmitted as an autosomal recessive trait. Affected patients may have as much as 40% methemoglobin but usually have no symptoms, although a mild compensatory polycythemia may be present. Patients with methemoglobinemia associated with a deficiency of diaphorase I respond readily to treatment with ascorbic acid and methylene blue (see next section), but treatment is not usually indicated.

3. Acquired Methemoglobinemia

Several compounds activate the oxidation of hemoglobin from the ferrous to the ferric state, forming methemoglobin. These include the nitrites and nitrates (contaminated water), chlorates, and quinones. Drugs in this group are the aniline dyes, sulfonamides, acetanilid, phenacetin, bismuth subnitrate, and potassium chlorate. Poisoning with a drug or chemical containing one of these substances should be suspected in any infant or child who presents with sudden cyanosis. Methemoglobin levels in such cases may be extremely high and can produce anoxia, dyspnea, unconsciousness, circulatory failure, and death. Young infants and newborns are more susceptible to acquired methemoglobinemia because their red cells have difficulty reducing hemoglobin, probably because their NADH methemoglobin reductase is transiently deficient. Infants with metabolic acidosis from diarrhea and dehydration or other causes also may develop methemoglobinemia.

Patients with the acquired form of methemoglobinemia respond dramatically to methylene blue in a dose of 1–2 mg/kg intravenously. For infants and young children, a smaller dose (1–1.5 mg/kg) is recommended. Ascorbic acid administered orally or intravenously also reduces methemoglobin, but the response is slower.
NEUTROPENIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Increased frequency of infections.
- Ulceration of oral mucosa and gingivitis.
- Normal numbers of red cells and platelets.

General Considerations

Neutropenia is an absolute neutrophil (granulocyte) count of less than 1500/μL in childhood, or below 1000/μL between ages 1 week and 2 years. During the first few days of life, an absolute neutrophil count of less than 3500 cells/μL may be considered neutropenia. Neutropenia results from absent or defective granulocyte stem cells, ineffective or suppressed myeloid maturation, decreased production of hematopoietic cytokines (eg, granulocyte colony-stimulating factor [G-CSF] or granulocyte-macrophage colony-stimulating factor [GM-CSF]), decreased marrow release, increased neutrophil destruction or consumption, or, in pseudo-neutropenia, from an increased neutrophil marginating pool (Table 28–5).

The most severe types of congenital neutropenia include reticular dysgenesis (congenital aleukocytosis), Kostmann syndrome (severe neutropenia with maturation defect in the marrow progenitor cells), Shwachman syndrome (neutropenia with pancreatic insufficiency), and cyclic neutropenia. Genetic mutations for Chédiak-Higashi syndrome, Kostmann and Shwachman syndromes, and cyclic neutropenia have been identified. Neutropenia may also be associated with storage and metabolic diseases and immunodeficiency states. The most common causes of neutropenia are viral infection or drugs resulting in decreased neutrophil production in the marrow or increased destruction or both. Severe bacterial infections may be associated with neutropenia. Although rare, neonatal alloimmune neutropenia can be severe and associated with risk for infection. Autoimmune neutropenia in the mother can result in passive transfer of antibody to the fetus and neutropenia in the neonate. Malignancies, osteopetrosis, marrow failure syndromes, and hypersplenism usually are not associated with isolated neutropenia.

Clinical Findings

A. Symptoms and Signs

Acute severe bacterial or fungal infection is the most significant complication of neutropenia. Although the risk is increased when the absolute neutrophil count is less than 500/μL, the actual susceptibility is variable and depends on the cause of neutropenia, marrow reserves, and other factors. The most common types of infection include septicemia, cellulitis, skin abscesses, pneumonia, and perirectal abscesses. Sinusitis, aphthous ulcers, gingivitis, and periodontal disease also cause significant problems. In addition to local signs and symptoms, patients may have chills, fever, and malaise. In most cases, the spleen and liver are not enlarged. Staphylococcus aureus and gram-negative bacteria are the most common pathogens.

B. Laboratory Findings

Neutrophils are absent or markedly reduced in the peripheral blood smear. In most forms of neutropenia or agranulocytosis, the monocytes and lymphocytes are normal and the red cells and platelets are not affected. The bone marrow usually shows a normal erythroid series, with adequate megakaryocytes, but a marked reduction in the myeloid cells or a significant delay in maturation of this series may be noted. Total cellularity may be decreased.

In the evaluation of neutropenia (eg, persistent, intermittent, cyclic), attention should be paid to the duration and pattern of neutropenia, the types of infections and their frequency, and phenotypic abnormalities on physical exam-

neutropenia. The neutrophils must be distinguished from myeloproliferative disorders such as chronic myelogenous leukemia and juvenile chronic myelogenous leukemia. In general, abnormalities involving other cell lines, the appearance of immature cells on the blood smear, and the presence of hepatosplenomegaly are important differentiating characteristics.

**DISORDERS OF NEUTROPHIL FUNCTION**

Neutrophils play a key role in host defenses. Circulating in capillary beds, they adhere to the vascular endothelium adjacent to sites of infection and inflammation. Moving...
between endothelial cells, the neutrophil migrates toward the offending agent. Contact with a microbe that is properly opsonized with complement or antibodies triggers ingestion, a process in which cytoplasmic streaming results in the formation of pseudopods that fuse around the invader, encasing it in a phagosome. During the ingestion phase, the oxidase enzyme system assembles and is activated, taking oxygen from the surrounding medium and reducing it to form toxic oxygen metabolites critical to microbicidal activity. Concurrently, granules from the two main classes (azurophil and specific) fuse and release their contents into the phagolysosome. The concentration of toxic oxygen metabolites (eg, hydrogen peroxide, hypochlorous acid, hydroxyl radical) and other compounds (eg, proteases, cationic proteins, cathepsins, defensins) increases dramatically, resulting in the death and dissolution of the microbe. Complex physiologic and biochemical processes support and control these functions. Defects in any of these processes may lead to inadequate cell function and an increased risk of infection.

Classification

Table 28–6 summarizes congenital neutrophil function defects. Recently described is a syndrome of severe neutrophil dysfunction and severe infections associated with a mutation in a GTPase signaling molecule, Rac2. New syndromes of innate immune dysfunction include defects in interferon and interleukin-12 receptor and signaling pathways, leading to monocye and macrophage dysfunction and toll-like receptor signaling pathways (interleukin-1 receptor-associated [IRAK] deficiency) associated with recurrent bacterial infections. Other congenital or acquired causes of mild to moderate neutrophil dysfunction include metabolic defects (eg, glycogen storage disease, diabetes mellitus, renal disease, and hypophosphatemia), viral infections, and certain drugs. Neutrophils from newborn infants have abnormal adherence, chemotaxis, and bactericidal activity. Cells from patients with thermal injury, trauma, and overwhelming infection have defects in cell motility and bactericidal activity similar to those seen in neonates.

Clinical Findings

Recurrent bacterial or fungal infections are the hallmark of neutrophil dysfunction. Although many patients will have infection-free periods, episodes of pneumonia, sinusitis, cellulitis, cutaneous and mucosal infections (including perianal or peritonsillar abscesses), and lymphadenitis are frequent. As with neutropenia, aphthous ulcers of mucous membranes, severe gingivitis, and periodontal disease are also major complications. In general, S aureus or gram-negative organisms are commonly isolated from infected sites; other organisms may be specifically associated with a defined neutrophil function defect. In some disorders, fungi account for an increasing number of infections. Deep or generalized infections, such as osteomyelitis, liver abscesses, sepsis, meningitis, and necrotic or gangrenous soft-tissue lesions, occur in specific syndromes (eg, leukocyte adherence deficiency or chronic granulomatous disease). Patients with severe neutrophil dysfunction may die in childhood from severe infections or associated complications. Table 28–6 summarizes pertinent laboratory findings.

Treatment

The mainstays of management of these disorders are anticipation of infections and aggressive attempts to identify the focus and causative agents. Surgical procedures to achieve these goals may be both diagnostic and therapeutic. Broad-spectrum antibiotics covering the range of possible organisms should be initiated without delay, switching to specific antimicrobial agents when the microbiologic diagnosis is made. When infections are unresponsive or they recur, granulocyte transfusions may be helpful.

Chronic management includes prophylactic antibiotics. Trimethoprim–sulfamethoxazole and some other antibiotics enhance the bactericidal activity of neutrophils from patients with chronic granulomatous disease. Some patients with Chédiak-Higashi syndrome improve clinically when given ascorbic acid. Recombinant γ-interferon decreases the number and severity of infections in patients with chronic granulomatous disease. Demonstration of this activity with one patient group raises the possibility that cytokines, growth factors, and other biologic response modifiers may be helpful in other conditions in preventing recurrent infections. Bone marrow transplantation has been attempted in most major congenital neutrophil dysfunction syndromes, and reconstitution with normal cells and cell function has been documented. Combining genetic engineering with autologous bone marrow transplantation may provide a future strategy for curing these disorders.

Prognosis

For mild to moderate defects, anticipation and conservative medical management ensure a reasonable outlook. For severe defects, excessive morbidity and significant mortality exist. In some diseases, the development of noninfectious complications, such as the lymphoproliferative phase of Chédiak-Higashi syndrome or inflammatory syndromes in chronic granulomatous disease, may influence prognosis.

LYMPHOCYTOSIS

From the first week up to the fifth year of life, lymphocytes are the most numerous leukocytes in human blood. The ratio then reverses gradually to reach the adult pattern of neutrophil predominance. An absolute lymphocytosis in childhood is associated with acute or chronic viral infections, pertussis, syphilis, tuberculosis, and hyperthyroidism. Other noninfectious conditions, drugs, and hypersensitivity and serum sickness–like reactions cause lymphocytosis.

Fever, upper respiratory symptoms, gastrointestinal complaints, and rashes are clues in distinguishing infectious from noninfectious causes. The presence of enlarged liver, spleen, or lymph nodes is crucial to the differential diagnosis, which includes acute leukemia and lymphoma. Most cases of infectious mononucleosis are associated with hepatosplenomegaly or adenopathy. The absence of anemia and thrombocytopenia helps to differentiate these disorders. Evaluation of the morphology of lymphocytes on peripheral blood smear is crucial. Infectious causes, particularly infectious mononucleosis, are associated with atypical features in the lymphocytes such as basophilic cytoplasm, vacuoles, finer and less-dense chromatin, and an indented nucleus. These features are distinct from the characteristic morphology associated with lymphoblastic leukemia. Lymphocytosis in childhood is most commonly associated with infections and resolves with recovery from the primary disease.

EOSINOPHILIA

Eosinophilia in infants and children is an absolute eosinophil count greater than 300/μL. Marrow eosinophil production is stimulated by the cytokine interleukin-5. Allergies, particularly eczema, are the most common primary causes of eosinophilia in children. Eosinophilia also occurs in drug reactions, with tumors (Hodgkin and non-Hodgkin lymphomas and brain tumors), and with immunodeficiency and histiocytosis syndromes. Increased eosinophil counts are a prominent feature of many invasive parasitic infections. Gastrointestinal disorders such as chronic hepatitis, ulcerative colitis, Crohn disease, and milk precipitin disease may be associated with eosinophilia. Increased blood eosinophil counts have been identified in several families without association with any specific illness. Rare causes of eosinophilia include the hypereosinophilic syndrome, characterized by counts greater than 1500/μL and organ involvement and damage (hepatosplenomegaly, cardiomyopathy, pulmonary fibrosis, and central nervous system injury). This is a disorder of middle-aged adults and is rare in children. Eosinophilic leukemia has been described, but its existence as a distinct entity is controversial.

Eosinophils are sometimes the last type of mature myeloid cell to disappear after marrow ablative chemotherapy. Increased eosinophil counts are associated with graft-versus-host disease after bone marrow transplantation, and elevations are sometimes documented during rejection episodes in patients who have solid organ grafts.

BLEEDING DISORDERS

Bleeding disorders may occur as a result of (1) quantitative or qualitative abnormalities of platelets, (2) quantitative or qualitative abnormalities in plasma procoagulant factors, (3) vascular abnormalities, or (4) accelerated fibrinolysis. The coagulation cascade and fibrinolytic system are shown in Figures 28–4 and 28–5.

The most critical aspect in evaluating the bleeding patient is obtaining detailed personal and family bleeding histories, including bleeding complications associated with dental interventions, surgeries, suture placement and removal, and trauma. Excessive mucosal bleeding is suggestive of a platelet disorder, von Willebrand disease, dysfibrinogenemia, or vasculitis. Bleeding into muscles and joints may be associated with a plasma procoagulant factor abnormality. In either scenario, the abnormality may be congenital or acquired. A thorough physical examination should be performed with

▲ Figure 28–4. The procoagulant system and formation of a fibrin clot. Vascular injury initiates the coagulation process by exposure of tissue factor (TF); the dashed lines indicate thrombin actions in addition to clotting of fibrinogen. The finely dotted lines indicate the feedback activation of the VII-TF complex by Xa and IXa. Ca++, calcium; HK, high molecular weight kininogen; PK, prekallikrein; PL, phospholipid. (Reproduced, with permission, from Goodnight SH, Hathaway WE (editors). Disorders of Hemostasis & Thrombosis: A Clinical Guide, 2nd ed. McGraw-Hill, 2001.)
special attention to the skin, oro- and nasopharynx, liver, spleen, and joints. Screening and diagnostic evaluation in patients with suspected bleeding disorders should initially include the following laboratory testing:

2. Activated partial thromboplastin time (aPTT) to assess clotting function of high molecular weight kininogen, prekallikrein, XII, XI, IX, VIII, X, V, II, and fibrinogen.
3. Platelet count and size determined as part of a CBC.
4. Platelet functional assessment by platelet function analyzer-100 (PFA-100), or template bleeding time.
5. Fibrinogen functional level by clotting assay.

The following laboratory tests may also be useful:

1. Thrombin time to measure the generation of fibrin from fibrinogen following conversion of prothrombin to thrombin, as well as the antithrombin effects of fibrin-split products and heparin. The thrombin time may be prolonged in the setting of a normal fibrinogen concentration if the fibrinogen is dysfunctional (ie, dysfibrinogenemia).
2. Euglobulin lysis time (ELT), if available, to evaluate for accelerated fibrinolysis if the preceding workup is non-revealing despite documented history of pathologic bleeding. If the ELT is shortened, assessment of plasminogen activator inhibitor-1 and α2-antiplasmin is warranted, as congenital deficiency in these fibrinolytic inhibitors may cause hyperfibrinolysis. In ill patients, measurement of fibrin degradation products may assist in the diagnosis of DIC.

### General Considerations

Acute idiopathic thrombocytopenic purpura (ITP) is the most common bleeding disorder of childhood. It occurs most frequently in children aged 2–5 years and often follows infection with viruses, such as rubella, varicella, measles, parvovirus, influenza, or EBV. Most patients recover spontaneously within a few months. Chronic ITP (> 6 months’ duration) occurs in 10–20% of affected patients. The thrombocytopenia results from clearance of circulating IgM- or IgG-coated platelets by the reticuloendothelial system. The spleen plays a predominant role in the disease by forming the platelet cross-reactive antibodies and sequestering the antibody-bound platelets.

### Clinical Findings

#### A. Symptoms and Signs

Onset of ITP is usually acute, with the appearance of multiple petechiae and ecchymoses. Epistaxis is also common at presentation. No other physical findings are usually present. Rarely, concurrent infection with EBV or CMV may cause hepatosplenomegaly or lymphadenopathy, simulating acute leukemia.

#### B. Laboratory Findings

1. **Blood**—The platelet count is markedly reduced (usually < 50,000/μL and often < 10,000/μL), and platelets frequently are of larger size on peripheral blood smear, suggesting acce-
CHAPTER 28

erated production of new platelets. The white blood count and differential are normal, and the hemoglobin concentration is preserved unless hemorrhage has been significant.

2. Bone marrow—The number of megakaryocytes is increased. Erythroid and myeloid cellularity is normal.

3. Other laboratory tests—Platelet-associated IgG or IgM, or both, may be demonstrated on the patient’s platelets or in the serum. PT and aPTT are normal.

**Differential Diagnosis**
Table 28–7 lists common causes of thrombocytopenia. ITP is a diagnosis of exclusion. Family history or the finding of predominantly giant platelets on the peripheral blood smear is helpful in determining whether thrombocytopenia is hereditary. Bone marrow examination should be performed if the history is atypical (ie, the child is not otherwise healthy, or if there is a family history of bleeding), if abnormalities other than purpura and petechiae are present on physical examination, or if other cell lines are affected on the CBC. The importance of performing a bone marrow examination prior to using corticosteroids in the treatment for ITP is controversial.

**Complications**
Severe hemorrhage and bleeding into vital organs are the feared complications of ITP. Intracranial hemorrhage is the most serious (but rarely seen) complication, occurring in less than 1% of affected children. The most important risk factors for hemorrhage are a platelet count less than 10,000/μL and mean platelet volume less than 8 fl.

**Treatment**

A. General Measures
Treatment is optional in most children in the absence of bleeding. Aspirin and other medications that compromise platelet function should be avoided. Bleeding precautions (eg, restriction from physical contact activities, use of helmets, etc) should be observed. Platelet transfusion should be avoided except in circumstances of life-threatening bleeding, in which case emergent splenectomy is to be pursued. In this setting, administration of corticosteroids and IVIG is also advisable.

B. Corticosteroids
Patients with clinically significant but non–life-threatening bleeding (ie, epistaxis, hematuria, and hematochezia) and those with a platelet count of less than 10,000/μL may benefit from prednisone at 2–4 mg/kg orally per day for 3–5 days, decreasing to 1–2 mg/kg/d for a total of 14 days. The dosage is then tapered and stopped. No further prednisone is given regardless of the platelet count unless significant bleeding recurs, at which time prednisone is administered in the smallest dose that achieves resolution of bleeding episodes (usually 2.5–5 mg twice daily). Follow-up continues until the steroid can again be discontinued, spontaneous remission occurs, or other therapeutic measures are instituted.

C. Intravenous Immunoglobulin (IVIG)
IVIG is the treatment of choice for severe, acute bleeding, and may also be used as an alternative or adjunct to corticosteroid treatment in both acute and chronic ITP of childhood. IVIG may be effective even when the patient is resistant to corticosteroids; responses are prompt and may last for several weeks. Most patients receive 1 g/kg/d for 1–3 days. Infusion time is typically 4–6 hours. Platelets may be given simultaneously during life-threatening hemorrhage but are rapidly destroyed. Adverse effects of IVIG are common, including transient neurologic complications (eg, headache, nausea, and aseptic meningitis) in one third of patients. These symptoms may mimic those of intracranial hemorrhage and necessitate radiologic evaluation of the brain. A transient decrease in neutrophil number may also be seen.

D. Anti-Rho(D) Immunoglobulin
This polyclonal immunoglobulin binds to the D antigen on red blood cells. The splenic clearance of anti-D–coated
red cells interferes with removal of antibody-coated platelets, resulting in improvement in thrombocytopenia. This approach is effective only in Rh(+) patients with a functional spleen. The time required for platelet increase is slightly longer than with IVIG. However, approximately 80% of Rh(+) children with acute or chronic ITP respond well. Significant hemolysis may occur transiently with an average hemoglobin concentration decrease of 0.8 g/dL. However, severe hemolysis occurs in 5% of treated children, and clinical and laboratory evaluation approximately 5 days following administration is warranted in all patients. Rho(D) immunoglobulin is less expensive and infused more rapidly than IVIG, but is more expensive than corticosteroids.

E. Splenectomy
Most children with chronic ITP have platelet counts greater than 30,000/μL. Up to 70% of such children spontaneously recover with a platelet count greater than 100,000/μL within 1 year. For the remainder, corticosteroids, IVIG, and anti-D immunoglobulin are typically effective treatment for acute bleeding. Splenectomy produces a response in 70–90%, but it should be considered only after persistence of significant thrombocytopenia for at least 1 year. Preoperative treatment with corticosteroids, IVIG, or anti-D immunoglobulin is usually indicated. Postoperatively, the platelet count may rise to 1 million/μL, but is not often associated with thrombotic complications in the pediatric age group. The risk of overwhelming infection (predominantly with encapsulated organisms) is increased after splenectomy, particularly in the young child. Therefore, the procedure should be postponed, if possible, until age 5 years. Administration of pneumococcal and H influenzae type b vaccines at least 2 weeks prior to splenectomy is recommended. Meningococcal vaccine, although controversial, may be considered. Penicillin prophylaxis should be started postoperatively and continued for 1–3 years.

F. Rituximab (Anti-CD20 Monoclonal Antibody)
The efficacy of treating childhood chronic ITP in several series and a phase I/II trial has been demonstrated; remission was observed in 40%. Because of significant adverse events, this therapy may be reserved for refractory cases with significant bleeding.

Prognosis
Ninety percent of children with ITP will have a spontaneous remission. Features associated with the development of chronic ITP include female gender, age greater than 10 years at presentation, insidious onset of bruising, and the presence of other autoantibodies. Older child- and adolescent-onset ITP is associated with an increased risk of chronic autoimmune diseases. Appropriate screening by history and laboratory studies (eg, antinuclear antibody) is warranted.

2. Thrombocytopenia in the Newborn
Thrombocytopenia is one of the most common causes of neonatal hemorrhage and should be considered in any newborn with petechiae, purpura, or other significant bleeding. Defined as a platelet count less than 150,000/μL, thrombocytopenia occurs in approximately 0.9% of unselected neonates. Several specific entities may be responsible (see Table 28–7); however, half of such neonates have alloimmune thrombocytopenia. Infection and DIC are the most common causes of thrombocytopenia in ill full-term newborns and in preterm newborns. In the healthy neonate, antibody-mediated thrombocytopenia (alloimmune or maternal autoimmune), viral syndromes, hyperviscosity, and major-vessel thrombosis are frequent causes of thrombocytopenia. Management is directed toward the underlying etiology.

A. Thrombocytopenia Associated with Platelet Alloantibodies (Neonatal Alloimmune Thrombocytopenia)
Platelet alloimmunization occurs in 1 in approximately 350 pregnancies. Unlike in Rh incompatibility, 30–40% of affected neonates are first-born. Thrombocytopenia is progressive over the course of gestation and worse with each subsequent pregnancy. Alloimmunization occurs when a platelet antigen of the infant differs from that of the mother and the mother is sensitized by fetal platelets that cross the placenta into the maternal circulation. In Caucasians, alloimmune thrombocytopenia is most often due to human platelet antigen (HPA)-1a incompatibility. Sensitization of a mother homozygous for HPA-1b to paternally acquired fetal HPA-1a antigen results in severe fetal thrombocytopenia in 1 in 1200 fetuses. Only 1 in 20 HPA-1a–negative fetuses of HPA-1a–negative mothers develop alloimmunization. The presence of antenatal maternal platelet antibodies on more than one occasion and their persistence into the third trimester is predictive of severe neonatal thrombocytopenia; a weak or undetectable antibody does not exclude thrombocytopenia. Severe intracranial hemorrhage occurs in 10–30% of affected neonates as early as 20 weeks’ gestation. Petechiae or other bleeding manifestations are usually present shortly after birth. The disease is self-limited, and the platelet count normalizes within 4 weeks.

If alloimmunization is associated with clinically significant bleeding, transfusion of platelet concentrates harvested...
from the mother is more effective than random donor platelets in increasing the platelet count. Transfusion with HPA-matched platelets from unrelated donors or treatment with IVIG or methylprednisolone has also been successful in raising the platelet count and achieving hemostasis. If thrombocytopenia is not severe and bleeding is absent, observation alone is often appropriate.

Intracranial hemorrhage in a previous child secondary to alloimmune thrombocytopenia is the strongest risk factor for severe fetal thrombocytopenia and hemorrhage in a subsequent pregnancy. Amniocentesis or chorionic villus sampling to obtain fetal DNA for platelet antigen typing is sometimes performed if the father is heterozygous for HPA-1a. If alloimmunization has occurred with a previous pregnancy, irrespective of history of intracranial hemorrhage, screening cranial ultrasound for hemorrhage should begin at 20 weeks’ gestation and be repeated regularly. In addition, cordocentesis should be performed at approximately 20 weeks’ gestation, with prophylactic transfusion of irradiated, leukoreduced, maternal platelet concentrates. If the fetal platelet count is less than 100,000/μL, the mother should be treated with weekly IVIG. Delivery by elective cesarean section is recommended if the fetal platelet count is less than 50,000/μL, to minimize the risk of intracranial hemorrhage associated with birth trauma.

B. Thrombocytopenia Associated with Idiopathic Thrombocytopenic Purpura in the Mother (Neonatal Autoimmune Thrombocytopenia)

Infants born to mothers with ITP or other autoimmune diseases (eg, antiphospholipid antibody syndrome or systemic lupus erythematosus) may develop thrombocytopenia as a result of transfer of antiplatelet IgG from the mother to the infant. Unfortunately, maternal and fetal platelet counts and maternal antiplatelet antibody levels are unreliable predictors of bleeding risk. Antenatal corticosteroid administration to the mother is generally instituted once maternal platelet count falls below 50,000/μL, with or without a concomitant course of IVIG.

Most neonates with neonatal autoimmune thrombocytopenia do not develop clinically significant bleeding, and thus treatment for thrombocytopenia is not often required. The risk of intracranial hemorrhage is 0.2–2%. If diffuse petechiae or minor bleeding are evident, a 1- to 2-week course of oral prednisone, 2 mg/kg/d, may be administered. If the platelet count remains consistently less than 20,000/μL or if severe hemorrhage develops, IVIG should be given (1 g/kg daily for 1–3 days). Platelet transfusions are only indicated for life-threatening bleeding, and may only be effective after removal of antibody by exchange transfusion. The platelet nadir is typically between the fourth to sixth day of life and improves significantly by 1 month; full recovery may take 2–4 months. Platelet recovery may be delayed in breast-fed infants because of transfer of IgG to the milk.

C. Neonatal Thrombocytopenia Associated with Infections

Thrombocytopenia is commonly associated with severe generalized infections during the newborn period. Between 50% and 75% of neonates with bacterial sepsis are thrombocytopenic. Intrauterine infections such as rubella, syphilis, toxoplasmosis, CMV, herpes simplex, enteroviruses, and parvovirus are often associated with thrombocytopenia. In addition to specific treatment for the underlying disease, platelet transfusions may be indicated in severe cases.

D. Thrombocytopenia Associated with Kaposiform Hemangioendotheliomas (Kasabach-Merritt Syndrome)

A rare but important cause of thrombocytopenia in the newborn is kaposiform hemangioendotheliomas, a benign neoplasm with histopathology distinct from that of classic infantile hemangiomas. Intense platelet sequestration in the lesion results in peripheral thrombocytopenia and may rarely be associated with a DIC-like picture and hemolytic anemia. The bone marrow typically shows megakaryocytic hyperplasia in response to the thrombocytopenia. Corticosteroids, α-interferon, and vincristine are all useful for reducing the size of the lesion and are indicated if significant coagulopathy is present, the lesion compresses a vital structure, or the lesion is cosmetically unacceptable. If consumptive coagulopathy is present, heparin or aminocaproic acid may be useful. Depending on the site, embolization may be an option. Surgery is often avoided because of the high risk of hemorrhage.

3. Disorders of Platelet Function

Individuals with platelet function defects typically develop skin and mucosal bleeding similar to that occurring in persons with thrombocytopenia. Historically, platelet function has been screened by measuring the bleeding time. If this is prolonged, in-vitro platelet aggregation is studied using agonists, such as adenosine diphosphate, collagen, arachidonic acid, and ristocetin, and simultaneous comparison with a normal control subject. While labor-intensive, platelet aggregometry remains important in selected clinical situations. The PFA-100 has become available to evaluate platelet dysfunction and von Willebrand disease, and has replaced the template bleeding time in many clinical laboratories. Unfortunately, none of these tests of platelet function is uniformly predictive of clinical bleeding severity.

Platelet dysfunction may be inherited or acquired, with the latter being more common. Acquired disorders of plate-
Plaque function may occur secondary to uremia, cirrhosis, sepsis, myeloproliferative disorders, congenital heart disease, and viral infections. Many pharmacologic agents decrease platelet function. The most common offending agents in the pediatric population are aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), synthetic penicillins, and valproic acid. In acquired platelet dysfunction, the PFA-100 closure time is typically prolonged with collagen-epinephrine, but normal with collagen-ADP.

The inherited disorders are due to defects in platelet-vessel interaction, platelet-platelet interaction, platelet granule content or release (including defects of signal transduction), thromboxane and arachidonic acid pathway, and platelet-procoagulant protein interaction. Individuals with hereditary platelet dysfunction generally have a prolonged bleeding time with normal platelet number and morphology by light microscopy. PFA-100 closure time, in contrast to that in acquired dysfunction, is typically prolonged with both collagen-ADP and collagen-epinephrine.

Congenital causes of defective platelet–vessel wall interaction include Bernard-Soulier syndrome. This condition is characterized by increased platelet size and decreased platelet number. The molecular defect in this autosomal recessive disorder is a deficiency or dysfunction of glycoprotein Ib-V-IX complex on the platelet surface resulting in impaired von Willebrand factor (vWF) binding, and hence, impaired platelet adhesion to the vascular endothelium.

Glanzmann thrombasthenia is an example of platelet-platelet dysfunction. In this autosomal recessive disorder, glycoprotein IIb-IIIa is deficient or dysfunctional. Platelets do not bind fibrinogen effectively and exhibit impaired aggregation. As in Bernard-Soulier syndrome, acute bleeding is treated by platelet transfusion.

Disorders involving platelet granule content include storage pool disease and Quebec platelet disorder. In individuals with storage pool disease, platelet-dense granules lack adenosine diphosphate and adenosine triphosphate and are often found to be low in number by electron microscopy. These granules are also deficient in Hermansky-Pudlak, Chédiak-Higashi, and Wiskott-Aldrich syndromes. Whereas deficiency of α-granules results in the gray platelet syndrome, Quebec platelet disorder is characterized by a normal platelet α-granule number, but with abnormal proteolysis of α-granule proteins and deficiency of platelet α-granule multimerin. Epinephrine-induced platelet aggregation is markedly impaired.

Platelet dysfunction has also been observed in other congenital syndromes, such as Down and Noonan syndromes, without a clear understanding of the molecular defect.

### Treatment

Acute bleeding in many individuals with acquired or selected congenital platelet function defects responds to therapy with desmopressin acetate, likely due to an induced release of vWF from endothelial stores. If this therapy is ineffective, or if the patient has Bernard-Soulier syndrome or Glanzmann syndrome, the mainstay of treatment for bleeding episodes is platelet transfusion. Recombinant VIIa has variable efficacy and may be helpful in platelet transfusion-refractory patients.

### INHERITED BLEEDING DISORDERS

Table 28–8 lists normal values for coagulation factors. The most common factor deficiencies are discussed in this section. Individuals with bleeding disorders should avoid exposure to medications that inhibit platelet function. Participation in contact sports should be considered in the context of the severity of the bleeding disorder.

#### 1. Factor VIII Deficiency

**Hemophilia A, Classic Hemophilia**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Bruising, soft-tissue bleeding, hemarthrosis.
- Prolonged activated partial thromboplastin time (aPTT).
- Reduced factor VIII activity.

**General Considerations**

Factor VIII activity is reported in units per milliliter, with 1 U/mL equal to 100% of the factor activity found in 1 mL of normal plasma. The normal range for factor VIII activity is 0.5–1.5 U/mL (50–150%). Hemophilia A occurs predominantly in males as an X-linked disorder. One third of cases are due to a new mutation. The incidence of factor VIII deficiency is 1:5000 male births.

**Clinical Findings**

**A. Symptoms and Signs**

Patients with severe hemophilia A (< 1% plasma factor VIII activity) have frequent spontaneous bleeding episodes involving skin, mucous membranes, joints, muscles, and viscera. In contrast, patients with mild hemophilia A (5–40% factor VIII activity) bleed only at times of trauma or surgery. Those with moderate hemophilia A (1% to < 5% factor VIII activity) typically have intermediate bleeding manifestations. The most crippling aspect of factor VIII deficiency is the tendency to develop recurrent hemarthroses that incite joint destruction.

Except as otherwise indicated values are mean ±2 SD or values in parentheses are lower limits (-2 SD or lower range); +, positive or present; −, decreased; ↑, increased; N, normal or no change; “,” values as ratio or subject/mean of reference range; α2-MG, α2-macroglobulin; α2-AP, α2-antiplasmin; ADP, adenosine diphosphate; AT, antithrombin; BT, bleeding time; C1IN, C1 esterase inhibitor; HK, high molecular weight kininogen; PAI, plasminogen activator inhibitor; PC, protein C; PreK, prekallikrein; PS, protein S; PT, prothrombin time; PTT, partial thromboplastin time; TCT, thrombin clotting time; TFPI, tissue factor pathway inhibitor; t-PA, tissue plasminogen activator; vWF, von Willebrand factor. Overall fibrinolysis is measured by euglobulin lysis time.

B. Laboratory Findings

Individuals with hemophilia A have a prolonged aPTT, except in some cases of mild deficiency. The prothrombin time (PT) is normal. The diagnosis is confirmed by finding decreased factor VIII activity with normal vWF activity. In two thirds of families of hemophilic patients, the females are carriers and some are mildly symptomatic. Carriers of hemophilia can be detected by determination of the ratio of factor VIII activity to vWF antigen and by molecular genetic techniques. In a male fetus or newborn with a family history of hemophilia A, cord blood sampling for factor VIII activity is accurate and important in subsequent care.

Complications

Intracranial hemorrhage is the leading disease-related cause of death among patients with hemophilia. Most intracranial hemorrhages in moderate to severe deficiency are spontaneous (ie, not associated with trauma). Hemarthroses begin early in childhood and, if recurrent, result in joint destruction (ie, hemophilic arthropathy). Large intramuscular hematomas can lead to a compartment syndrome with resultant muscle and nerve death. Although these complications are most common in severe hemophilia A, they may be experienced by individuals with moderate or mild disease. A serious complication of hemophilia is the development of an acquired circulating antibody to factor VIII after treatment with factor VIII concentrate. Such factor VIII inhibitors develop in 15–25% of patients with severe hemophilia A, and may be amenable to desensitization with regular factor VIII infusion with or without immunosuppressive therapy. In recent years, recombinant factor VIIa has become a therapy of choice for treatment of acute hemorrhage in patients with hemophilia A and a high-titer inhibitor.

In prior decades, therapy-related complications in hemophilia A have included infection with the human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV). Through more stringent donor selection, the implementation of sensitive screening assays, the use of heat- or chemical viral inactivation methods, and the development of recombinant products, the risk of these infections is minimal. Inactivation methods do not eradicate viruses lacking a lipid envelope, however, so that transmission of parvovirus and hepatitis A remains a concern with the use of plasma-derived products. Immunization with hepatitis A and hepatitis B vaccines is recommended for all hemophilia patients.

Treatment

The general aim of management is to raise the factor VIII activity to prevent or stop bleeding. Some patients with mild factor VIII deficiency may respond to desmopressin via release of endothelial stores of factor VIII and vWF into plasma; however, most patients require administration of exogenous factor VIII to achieve hemostasis. The in-vivo half-life of factor VIII is generally 8–12 hours but may exhibit considerable variation among individuals depending on comorbid conditions. Non–life-threatening, non–limb-threatening hemorrhage is treated initially with 20–30 U/kg of factor VIII, to achieve a rise in plasma factor VIII activity to 40–60%. Large joint hemorrhages and life- or limb-threatening hemorrhage is treated initially with approximately 50 U/kg of factor VIII, targeting a rise to 100% factor VIII activity. Subsequent doses are determined according to the site and extent of bleeding and the clinical response. Doses are rounded to the nearest whole vial size. In circumstances of suboptimal clinical response, recent change in bleeding frequency, or comorbid illness, monitoring the plasma factor VIII activity response may be warranted. For most instances of non–life-threatening hemorrhage in experienced patients with moderate or severe hemophilia A, treatment can be administered at home, provided adequate intravenous access exists and close contact is maintained with the hemophilia clinician team.

Prophylactic factor VIII infusions (eg, two or three times weekly) may prevent the development of arthropathy in severe hemophiliacs, and this approach is becoming more common in pediatric hemophilia care.

Prognosis

The development of safe and effective therapies for hemophilia A has resulted in improved long-term survival in recent decades. In addition, more aggressive management and the coordination of comprehensive care through hemophilia centers have greatly improved quality of life and level of function.

2. Factor IX Deficiency
(Hemophilia B, Christmas Disease)

The mode of inheritance and clinical manifestations of factor IX deficiency are the same as those of factor VIII deficiency. Hemophilia B is 15–20% as prevalent as hemophilia A. As in factor VIII deficiency, factor IX deficiency is associated with a prolonged aPTT, but the PT and thrombin time are normal. However, the aPTT is slightly less sensitive to factor IX deficiency than factor VIII deficiency. Diagnosis of hemophilia B is made by assaying factor IX activity, and severity is determined similarly to factor VIII deficiency. In general, clinical bleeding severity correlates less well with factor activity in hemophilia B than in hemophilia A.

The mainstay of treatment in hemophilia B is exogenous factor IX. Unlike factor VIII, about 50% of the administered dose of factor IX diffuses into the extravascular space. Therefore, 1 U/kg of plasma-derived factor IX concentrate or
recombinant factor IX is expected to increase plasma factor IX activity by approximately 1%. Factor IX typically has a half-life of 20–22 hours in vivo, but due to variability, therapeutic monitoring may be warranted. As for factor VIII products, viral inactivation techniques for plasma-derived factor IX concentrates appear effective in eradicating HIV, HBV, and HCV. Only 1–3% of persons with factor IX deficiency develop an inhibitor to factor IX, but patients may be at risk for anaphylaxis when receiving exogenous factor IX. The prognosis for persons with factor IX deficiency is comparable to that of patients with factor VIII deficiency. Gene therapy research efforts are ongoing for both hemophilies.

Shapiro AD: The safety and efficacy of recombinant human blood coagulation factor IX in previously untreated patients with severe or moderately severe hemophilia B. Blood 2005;105:518 [PMID: 15383463].

3. Factor XI Deficiency (Hemophilia C)

Factor XI deficiency is a genetic, autosomally transmitted coagulopathy, typically of mild to moderate clinical severity. Cases of factor XI deficiency account for less than 5% of all hemophilia patients. Homozygotes generally bleed at surgery or following severe trauma, but do not commonly have spontaneous hemarthroses. In contrast to factor VIII and IX deficiencies, factor XI activity is least predictive of bleeding risk. Although typically mild, pathologic bleeding may be seen in heterozygous individuals with factor XI activity as high as 60%. The aPTT is often considerably prolonged. In individuals with deficiency of both plasma and platelet-associated factor XI, the PFA-100 may also be prolonged. Management typically consists of perioperative prophylaxis and episodic therapy for acute hemorrhage. Treatment includes infusion of fresh frozen plasma (FFP); platelet transfusion may also be useful for acute hemorrhage in patients with deficiency of platelet-associated factor XI. Desmopressin has been used in some cases. The prognosis for an average life span in patients with factor XI deficiency is excellent.

4. Other Inherited Bleeding Disorders

Other hereditary single clotting factor deficiencies are rare. Transmission is generally autosomal. Homozygous individuals with a deficiency or structural abnormality of prothrombin, factor V, factor VII, or factor X may have excessive bleeding.

Persons with dysfibrinogenemia (ie, structurally or functionally abnormal fibrinogen) may develop recurrent venous thromboembolic episodes or bleeding. Immunologic assay of fibrinogen is normal, but clotting assay may be low and the thrombin time prolonged. The PT and aPTT may be prolonged. Cryoprecipitate, which is rich in fibrinogen, is the treatment of choice, given the present lack of availability of a plasma-derived or recombinant fibrinogen product in the United States.

Afibrinogenemia resembles hemophilia clinically but has an autosomal recessive inheritance. Affected patients can experience a variety of bleeding manifestations, including mucosal bleeding, ecchymoses, hematomas, hemarthroses, and intracranial hemorrhage, especially following trauma. Fatal umbilical cord hemorrhage has been reported in neonates. The PT, aPTT, and thrombin time are all prolonged. A severely reduced fibrinogen concentration in an otherwise well child is confirmatory of the diagnosis. As in dysfibrinogenemia, cryoprecipitate infusion is used for surgical prophylaxis and for acute hemorrhage.

VON WILLEBRAND DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Easy bruising and epistaxis from early childhood.
- Menorrhagia.
- Prolonged PFA-100 (or bleeding time); normal platelet count; absence of acquired platelet dysfunction.
- Reduced activity or abnormal structure of vWF.

General Considerations

d von Willebrand disease (vWD) is the most common inherited bleeding disorder among Caucasians, with a prevalence of 1%. vWF is a protein present as a multimeric complex in plasma, which binds factor VIII and is a cofactor for platelet adhesion to the endothelium. An estimated 70–80% of all patients with vWD have classic vWD (type 1), which is caused by a partial quantitative deficiency of vWF. vWD type 2 involves a qualitative deficiency of (ie, dysfunctional) vWF, and vWD type 3 is characterized by a nearly complete deficiency of vWF. The majority (> 80%) of individuals with type 1 disease are asymptomatic. vWD is most often transmitted as an autosomal dominant trait, but can be autosomal recessive. The disease can also be acquired, developing in association with hypothyroidism, Wilms tumor, cardiac disease, renal disease, or systemic lupus erythematosus and in individuals receiving valproic acid. Acquired vWD is most often caused by the development of an antibody to vWF or increased turnover of vWF.
Clinical Findings
A. Symptoms and Signs
A history of increased bruising and excessive epistaxis is often present. Prolonged bleeding also occurs with trauma or at surgery. Menorrhagia is often a presenting finding in females.

B. Laboratory Findings
PT is normal, and aPTT is sometimes prolonged. Prolongation of the PFA-100 or bleeding time is usually present since vWF plays a role in platelet adherence to endothelium. Platelet number may be decreased in type 2b vWD. Factor VIII and vWF antigen are decreased in types 1 and 3, but may be normal in type 2 vWD. vWF activity (eg, ristocetin cofactor or collagen binding) is decreased in all types. Since normal vWF antigen levels vary by blood type (type O normally has lower levels), blood type must be determined. Complete laboratory classification requires vWF multimer assay. The diagnosis requires confirmation of laboratory testing and bleeding history is often helpful when present.

Treatment
The treatment to prevent or halt bleeding for most patients with vWD types 1 and 2 is desmopressin acetate, which causes release of vWF from endothelial stores. Desmopressin may be administered intravenously at a dose of 0.3 mcg/kg diluted in at least 20–30 mL of normal saline and given over 20–30 minutes. This dose typically elicits a three- to fivefold rise in plasma vWF. A high-concentration desmopressin nasal spray (150 mcg/spray), different than the preparation used for enuresis, may be used. Because response to vWF is variable among patients, factor VIII and vWF activities are typically measured before and 60 minutes after infusion, if no recent response has been measured. Desmopressin may cause fluid shifts, hyponatremia, and seizures in children younger than 2 years of age. Because release of stored vWF is limited, tachyphylaxis often occurs with desmopressin.

If further therapy is indicated, vWF-replacement therapy (eg, plasma-derived concentrate) is recommended; such therapy is also used in patients with type 1 or 2a vWD who exhibit suboptimal laboratory response to desmopressin, and for all individuals with type 2b or 3 vWD. Anti fibrinolytic agents (eg, epsilon-aminocaproic acid) may be useful for control of mucosal bleeding. Topical thrombin and fibrin glue may also be of benefit, although antibodies that inhibit clotting proteins have been described. Estrogen-containing contraceptive therapy may be helpful for menorrhagia.

Prognosis
With the availability of effective treatment and prophylaxis for bleeding, life expectancy in vWD is normal.

ACQUIRED BLEEDING DISORDERS
1. Disseminated Intravascular Coagulation (DIC)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Presence of disorder known to trigger DIC.
- Evidence for consumptive coagulopathy (prolonged aPTT, PT, or thrombin time; increase in FSP (fibrin-fibrinogen split products); decreased fibrinogen or platelets).

General Considerations
DIC is an acquired pathologic process characterized by tissue factor–mediated diffuse coagulation activation in the host. DIC involves dysregulated, excessive thrombin generation, with consequent intravascular fibrin deposition and consumption of platelets and procoagulant factors. Microthrombi, composed of fibrin and platelets, may produce tissue ischemia and end-organ damage. The fibrinolytic system is frequently activated in DIC, leading to plasmin-mediated destruction of fibrin and fibrinogen; this results in fibrin-fibrinogen degradation products (FDPs) which exhibit anticoagulant and platelet-inhibitory functions. DIC commonly accompanies severe infection and other critical illnesses in infants and children. Conditions known to trigger DIC include endothelial damage (eg, endotoxin, virus), tissue necrosis (eg, burns), diffuse ischemic injury (eg, shock, hypoxia acidosis), and systemic release of tissue procoagulants (eg, certain cancers, placental disorders).

Clinical Findings
A. Symptoms and Signs
Signs of DIC may include (1) signs of shock, often including end-organ dysfunction, (2) diffuse bleeding tendency (eg, hematuria, melena, purpura, petechiae, persistent oozing from needle punctures or other invasive procedures), and (3) evidence of thrombotic lesions (eg, major vessel thrombosis, purpura fulminans).

B. Laboratory Findings
Tests that are most sensitive, easiest to perform, most useful for monitoring, and best reflect the hemostatic capacity of the patient are the PT, aPTT, platelet count, fibrinogen, and fibrin-fibrinogen split products. The PT and aPTT are typically prolonged and the platelet count and fibrinogen
concentration may be decreased. However, in children, the fibrinogen level may be normal until late in the course. Levels of fibrin–fibrinogen split products are increased, and elevated levels of d-dimer, a cross-linked fibrin degradation byproduct, may be helpful in monitoring the degree of activation of both coagulation and fibrinolysis. However, d-dimer is nonspecific and may be elevated in the context of a triggering event (eg, severe infection) without concomitant DIC. Often, physiologic inhibitors of coagulation, especially antithrombin III and protein C, are consumed, predisposing to thrombosis. The specific laboratory abnormalities in DIC may vary with the triggering event and the course of illness.

**Differential Diagnosis**

DIC can be difficult to distinguish from coagulopathy of liver disease (ie, hepatic synthetic dysfunction), especially when the latter is associated with thrombocytopenia secondary to portal hypertension and hypersplenism. Generally, factor VII activity is decreased markedly in liver disease (due to deficient synthesis of this protein, which has the shortest half-life among the procoagulant factors), but only mildly to moderately decreased in DIC (due to consumption). Factor VIII activity is often normal or even increased in liver disease, but decreased in DIC.

**Treatment**

**A. Therapy for Underlying Disorder**

The most important aspect of therapy in DIC is the identification and treatment of the triggering event. If the pathogenic process underlying DIC is reversed, often no other therapy is needed for the coagulopathy.

**B. Replacement Therapy for Consumptive Coagulopathy**

Replacement of consumed procoagulant factors with FFP and of platelets via platelet transfusion is warranted in the setting of DIC with hemorrhagic complications, or as periprocedural bleeding prophylaxis. Infusion of 10–15 mL/kg FFP typically raises procoagulant factor activities by approximately 10–15%. Cryoprecipitate can also be given as a rich source of fibrinogen; one bag of cryoprecipitate per 3 kg in infants or one bag of cryoprecipitate per 6 kg in older children typically raises plasma fibrinogen concentration by 75–100 mg/dL.

**C. Anticoagulant Therapy for Coagulation Activation**

Continuous intravenous infusion of unfractionated heparin is sometimes given in order to attenuate coagulation activation and consequent consumptive coagulopathy. The rationale for heparin therapy is to maximize the efficacy of, and minimize the need for, replacement of procoagulants and platelets; however, clinical evidence demonstrating benefit of heparin in DIC is lacking. Heparin dosing is provided in the section on thrombosis treatment.

**D. Specific Factor Concentrates**

A nonrandomized pilot study of antithrombin concentrate in children with DIC and associated acquired antithrombin deficiency demonstrated favorable outcomes, suggesting that replacement of this consumed procoagulant may be of benefit. Protein C concentrate has also shown promise in two small pilot studies of meningococcal-associated DIC with purpura fulminans. Activated protein C has reduced mortality in septic adults in a large randomized multicenter trial; an international pediatric trial is ongoing.

**2. Liver Disease**

The liver is the major synthetic site of prothrombin, fibrinogen, high molecular weight kininogen, and factors V, VII, IX, X, XI, XII, and XIII. In addition, plasminogen and the physiologic anticoagulants (antithrombin III, protein C, and protein S) are hepatically synthesized. α2-Antiplasmin, a regulator of fibrinolysis, is also produced in the liver. Deficiency of factor V and the vitamin K–dependent factors (II, VII, IX, and X) is most often a result of decreased hepatic synthesis and is manifested by a prolonged PT and often a prolonged aPTT. Extravascular loss and increased consumption of clotting factors may contribute to PT and aPTT prolongation. Fibrinogen production is often decreased, or an abnormal fibrinogen (dysfibrinogen) containing excess sialic acid residues may be synthesized, or both. Hypofibrinogenemia or dysfibrinogenemia is associated with prolongation of thrombin time and reptilase time. FDPs and d-dimers may be present because of increased fibrinolysis, particularly in the setting of chronic hepatitis or cirrhosis. Thrombocytopenia secondary to hypersplenism may occur. DIC and coagulopathy of liver disease also mimic vitamin K deficiency; however, vitamin K deficiency has normal factor V activity. Treatment of acute bleeding in the setting of coagulopathy of liver disease consists of replacement with FFP and platelets. Desmopressin may shorten the bleeding time and aPTT in patients with chronic liver disease, but its safety has not been well established. Recombinant VIIa also is efficacious for life-threatening hemorrhage.

**3. Vitamin K Deficiency**

The newborn period is characterized by physiologically depressed activity of the vitamin K–dependent factors (II, VII, IX, and X). If vitamin K is not administered at birth, a bleeding diathesis previously called hemorrhagic disease of the newborn, now termed vitamin K deficiency bleeding (VKDB), may develop. Outside of the newborn period, vitamin K deficiency may occur as a consequence of inadequate intake, excess loss, inadequate formation of active metabolites, or competitive antagonism.
HEMATOLOGIC DISORDERS

One of three patterns is seen in the neonatal period:

1. Early VKDB of the newborn occurs within 24 hours of birth and is most often manifested by cephalohematoma, intracranial hemorrhage, or intra-abdominal bleeding. Although occasionally idiopathic, it is most often associated with maternal ingestion of drugs that interfere with vitamin K metabolism (eg, warfarin, phenytoin, isoniazid, and rifampin). Early VKDB occurs in 6–12% of neonates born to mothers who take these medications without receiving vitamin K supplementation. The disorder is often life-threatening.

2. Classic VKDB occurs at 24 hours to 7 days of age and usually is manifested as gastrointestinal, skin, or mucosal bleeding. Bleeding after circumcision may occur. Although occasionally associated with maternal drug usage, it most often occurs in well infants who do not receive vitamin K at birth and are solely breast fed.

3. Late neonatal VKDB occurs on or after day 8. Manifestations include intracranial, gastrointestinal, or skin bleeding. This disorder is often associated with fat malabsorption (eg, in chronic diarrhea) or alterations in intestinal flora (eg, with prolonged antibiotic therapy). Like classic VKDB, late VKDB occurs almost exclusively in breast-fed infants.

The diagnosis of vitamin K deficiency is suspected based on the history, physical examination, and laboratory results. The PT is prolonged out of proportion to the aPTT (also prolonged). The thrombin time becomes prolonged late in the course. The platelet count is normal. This laboratory profile is similar to the coagulopathy of acute liver disease, but with normal fibrinogen level and absence of hepatic transaminase elevation. The diagnosis of vitamin K deficiency is confirmed by a demonstration of noncarboxylated proteins in the absence of vitamin K in the plasma and by clinical and laboratory responses to vitamin K. Intravenous or subcutaneous treatment with vitamin K should be given immediately and not withheld while awaiting test results. In the setting of severe bleeding, additional acute treatment with FFP or recombinant factor VIIa may be indicated.

4. Uremia

Uremia is frequently associated with acquired platelet dysfunction. Bleeding occurs in approximately 50% of patients with chronic renal failure. The bleeding risk conferred by platelet dysfunction associated with metabolic imbalance may be compounded by decreased vWF activity and procoagulant deficiencies (eg, factor II, XII, XI, IX) due to increased urinary losses of these proteins in some settings of renal insufficiency. In accordance with platelet dysfunction, uremic bleeding is typically characterized by purpura, epistaxis, menorrhagia, or gastrointestinal hemorrhage. Acute bleeding may be managed with infusion of desmopressin acetate, factor VIII concentrates containing vWF, or cryoprecipitate with or without coadministration of FFP. Red cell transfusion may be required. Prophylactic administration of erythropoietin before the development of severe anemia appears to decrease the bleeding risk. Recombinant VIIa may be useful in refractory bleeding.

VASCULAR ABNORMALITIES ASSOCIATED WITH BLEEDING

1. Henoch-Schönlein Purpura (Anaphylactoid Purpura)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Purpuric cutaneous rash.
- Migratory polyarthritis or polyarthralgias.
- Intermittent abdominal pain.
- Nephritis.

General Considerations

Henoch-Schönlein purpura (HSP), the most common type of small vessel vasculitis in children, primarily affects boys 2–7 years of age. Occurrence is highest in the spring and fall, and upper respiratory infection precedes the diagnosis in two thirds of children.

Leukocytoclastic vasculitis in HSP principally involves the small vessels of the skin, gastrointestinal tract, and kidneys, with deposition of IgA immune complexes. The most common and earliest symptom is palpable purpura, which results from extravasation of erythrocytes into the tissue surrounding the involved venules. Antigens from group A β-hemolytic streptococci and other bacteria, viruses, drugs, foods, and insect bites have been proposed as inciting agents.

Clinical Findings

A. Symptoms and Signs

Skin involvement may be urticarial initially, progresses to a maculopapules, and coalesce to a symmetrical, palpable purpuric rash distributed on the legs, buttocks, and elbows. New lesions may continue to appear for 2–4 weeks, and may extend to involve the entire body. Two thirds of patients develop migratory polyarthralgias or polyarthritides, primarily of the ankles and knees. Intermittent, sharp abdominal pain occurs in approximately 50% of patients, and hemorrhage and edema of the small intestine can often be demonstrated. Intussuscep-
tion may develop. From 25–50% of those affected develop renal involvement in the second or third week of illness with either a nephritic or, less commonly, nephrotic picture. Hypertension may accompany the renal involvement. In males, testicular torsion may also occur, and neurologic symptoms are possible due to small vessel vasculitis.

B. Laboratory Findings

The platelet count is normal or elevated, and other screening tests of hemostasis and platelet function are typically normal. Urinalysis frequently reveals hematuria, and sometimes proteinuria. Stool may be positive for occult blood. The anti-streptolysin O (ASO) titer is often elevated and the throat culture positive for group A β-hemolytic streptococci. Serum IgA may be elevated.

Differential Diagnosis

The rash of septicaemia (especially meningococcemia) may be similar to skin involvement in HSP, although the distribution tends to be more generalized. The possibility of trauma should be considered in any child presenting with purpura. Other vasculitides should also be considered. The lesions of thrombotic thrombocytopenic purpura are not palpable.

Treatment

Generally, treatment is supportive. NSAIDs may be useful for the arthritis. Corticosteroid therapy may provide symptomatic relief for severe gastrointestinal or joint manifestations but does not alter skin or renal manifestations. If culture for group A β-hemolytic streptococci is positive or if the ASO titer is elevated, a therapeutic course of penicillin is warranted.

Prognosis

The prognosis for recovery is generally good, although symptoms frequently (25–50%) recur over a period of several months. In patients who develop renal manifestations, microscopic hematuria may persist for years. Progressive renal failure occurs in less than 5% of patients with HSP, with an overall fatality rate of 3%.

2. Collagen Disorders

Mild to life-threatening bleeding occurs with some types of Ehlers-Danlos syndrome, the most common inherited collagen disorder. Ehlers-Danlos syndrome is characterized by joint hypermobility, skin extensibility, and easy bruising. Coagulation abnormalities may sometimes be present, including platelet dysfunction and deficiencies of coagulation factors VIII, IX, XI, and XIII. However, bleeding and easy bruising, in most instances, relates to fragility of capillaries and compromised vascular integrity. Individuals with Ehlers-Danlos syndrome types 4 and 6 are at risk for aortic dissection and spontaneous rupture of aortic aneurysms. Surgery should be avoided for patients with Ehlers-Danlos syndrome, as should medications that induce platelet dysfunction.

THROMBOTIC DISORDERS

General Considerations

Although uncommon in children, thrombotic disorders are being recognized with increasing frequency, particularly with heightened physician awareness and improved survival in pediatric intensive care settings. Several clinical conditions have a potential association with thrombotic events in childhood (see Clinical Risk Factors, below).

Clinical Findings

Initial evaluation of the child who has thrombosis includes an assessment for potential triggering factors, as well as a family history of thrombosis and early cardiovascular or cerebrovascular disease.

A. Clinical Risk Factors

Clinical risk factors are present in more than 90% of children with acute venous thromboembolic events (VTEs). These conditions include the presence of an indwelling vascular catheter, cardiac disease, malignancy, infection, trauma, surgery, immobilization, collagen-vascular or chronic inflammatory disease, renal disease, and sickle cell anemia.

1. Inherited thrombophilia (hypercoagulability) states

A. Protein C deficiency—Protein C is a vitamin K–dependent protein that is normally activated by thrombin bound to thrombomodulin and inactivates activated factors V and VIII. In addition, activated protein C promotes fibrinolysis. Two phenotypes of hereditary protein C deficiency exist. Heterozygous individuals with autosomal dominant protein C deficiency often present with VTEs as young adults, but the disorder may manifest during childhood or in later adulthood. In the absence of VTEs, prophylaxis is limited to periods of increased prothrombotic risk. Homozygous or compound heterozygous protein C deficiency is rare but phenotypically severe. Affected children generally present within the first 12 hours of life with purpura fulminans and/or VTEs. Retinal thrombosis may result in blindness. Prompt protein C replacement by infusion of FFP every 6–12 hours, or of protein C concentrate (if available), along with therapeutic heparin administration is recommended. Subsequent management requires chronic anticoagulation
with warfarin or protein C concentrate. Recurrent VTEs are common, especially during periods of subtherapeutic anticoagulation or in the presence of conditions associated with increased prothrombotic risk.

b. Protein S deficiency—Protein S is a cofactor for protein C. Neonates with homozygous protein S deficiency have a course similar to those with homozygous or compound heterozygous protein C deficiency. Lifelong warfarin therapy is indicated in severe deficiency, or in heterozygous individuals who have experienced recurrent VTEs. Efforts must be made to distinguish from these conditions from acquired deficiency.

c. Antithrombin III (ATIII) deficiency—ATIII is the most important physiologic inhibitor of thrombin and inhibits activated factors IX, X, XI, and XII. ATIII deficiency is transmitted in an autosomal dominant pattern and is associated with VTEs, typically with onset in adolescence or young adulthood. Therapy for acute VTEs involves replacement with antithrombin concentrate (if available) and therapeutic anticoagulation. The efficiency of heparin may be significantly diminished in the setting of severe ATIII deficiency and anticoagulation with warfarin required. Patients with recurrent VTEs are maintained on lifelong warfarin.

d. Factor V Leiden mutation—An amino acid substitution in the gene coding for factor V results in factor V Leiden, a factor V polymorphism that is resistant to inactivation by activated protein C. The most common cause of activated protein C resistance in Caucasians, factor V Leiden is present in approximately 5% of the Caucasian population, 20% of Caucasian adults with deep vein thrombosis, and 40–60% of those with a family history of VTEs. VTEs occur in both heterozygous and homozygous individuals. In the former case, thrombosis is typically triggered by a clinical risk factor (or else develops in association with additional thrombophilia traits), whereas in the latter case, it is often spontaneous. Population studies suggest that the risk of VTEs is increased 7-fold in the setting of heterozygous factor V Leiden, 35-fold among heterozygous individuals taking the oral contraceptives, and 80-fold in those homozygous for factor V Leiden.

e. Prothrombin mutation—The 20210 glutamine to alanine mutation in the prothrombin gene is a relatively common polymorphism in Caucasians that enhances its activation to thrombin. In heterozygous form, prothrombin 20210 has been associated with a threefold increased risk for VTE.

f. Other inherited disorders—Qualitative abnormalities of fibrinogen (dysfibrinogenemias) are usually inherited in an autosomal dominant manner. Most individuals with dysfibrinogenemia are asymptomatic. Some patients experience bleeding, while others develop venous or arterial thrombosis. The diagnosis is suggested by a prolonged thrombin time with a normal fibrinogen concentration. Hyperhomocysteinemia can be an inherited or an acquired condition and is associated with an increased risk for both arterial and venous thromboses. In children, it may also serve as a risk factor for ischemic arterial stroke. However, hyperhomocysteinemia is quite uncommon in the setting of dietary folate supplementation (as in the United States), and is observed almost uniquely in cases of metabolic disease (eg, homocystinuria). Furthermore, methylene tetrahydrofolate reductase receptor mutations do not appear to constitute a risk factor for thrombosis in U.S. children when homocysteine is not elevated.

Lipoprotein(a) is a lipoprotein with homology to plasminogen. In-vitro studies suggest that lipoprotein(a) may both promote atherothrombosis and inhibit fibrinolysis. Case-control studies suggest that elevated plasma concentrations of lipoprotein(a) are associated with an increased odds of VTEs and ischemic arterial stroke in children.

Increased factor VIII may be demonstrated in patients with acute VTEs. This increase has been implicated as a risk factor for VTEs in adults and may be familial.

2. Acquired disorders

a. Antiphospholipid antibodies—The development of antiphospholipid antibodies is the most common form of acquired thrombophilia in children. Antiphospholipid antibodies, which include the lupus anti-coagulant, anticardiolipin antibodies, and β2-glycoprotein-1 antibodies, have become increasingly implicated in VTEs. The lupus anti-coagulant is demonstrated in vitro by its inhibition of phospholipid-dependent coagulation assays (eg, aPTT and dilute Russell viper venom time), whereas immunologic techniques (eg, enzyme-linked immunosorbent assays) are often used to detect anticardiolipin and β2-glycoprotein-1 antibodies. Although common in persons with autoimmune diseases such as systemic lupus erythematosus, antiphospholipid antibodies may also develop following certain drug exposures, infection, acute inflammation, and lymphoproliferative diseases. Sometimes VTEs and antiphospholipid antibodies may predate other signs of lupus for long periods of time. Viral illness is a common precipitant in children, and in many cases, the inciting infection may be asymptomatic.

If an antiphospholipid antibody persists for 6–12 weeks following the acute thrombotic event, the diagnosis of this syndrome is confirmed and anticoagulation should be continued at least until the antiphospholipid antibody becomes undetectable. In addition, consideration should be given to long-term anticoagulation.

b. Deficiencies of intrinsic anticoagulants—Acquired deficiencies of proteins C and S and ATIII may occur in the clinical context of excessive consumption, including sepsis, DIC, major-vessel or extensive VTE, and post–bone marrow transplant sinusoidal obstruction syndrome (formerly termed hepatic veno-occlusive disease). Pilot studies in children have suggested a possible therapeutic role for antithrombin or protein C concentrates in sepsis associated DIC and severe post-transplant sinusoidal obstruction syndrome.
C. Acute Phase Reactants—As part of the acute phase response, elevations in plasma fibrinogen concentration, plasma factor VIII, and platelet count may occur, all of which may contribute to an acquired prothrombotic state. Reactive thrombocytosis is rarely associated with VTEs in children when the platelet count is less than 1 million/µL.

B. Symptoms and Signs
Presenting features of thrombosis vary with the anatomic site, extent of vascular involvement, degree of vaso-occlusion, and presence of end-organ dysfunction. The classic presentation of deep venous thrombosis of an upper or lower extremity is painful acute or subacute extremity swelling, while that for pulmonary embolism commonly involves dyspnea and pleuritic chest pain, and in cerebral sinovenous thrombosis often includes severe or persistent headache, with or without neurologic deficit. Arterial thrombosis of the lower extremity (eg, neonatal umbilical artery catheter–associated), as well as vasospasm without identified thrombosis, often manifests with diminished distal pulses and dusky discoloration of the limb.

C. Laboratory Findings
A comprehensive laboratory investigation for thrombophilia (ie, hypercoagulability) is recommended by the International Society on Thrombosis and Haemostasis in order to disclose possible underlying congenital or acquired abnormalities that may affect acute or long-term management. Testing for intrinsic anticoagulant deficiencies (proteins C and S and ATIII), procoagulant factor excesses or activators (eg, factor VIII and antiphospholipid antibodies), genetic mutations mediating enhanced procoagulant activity or reduced sensitivity to inactivation (factor V Leiden and prothrombin 20210 polymorphisms), biochemical mediators of endothelial damage (homocysteine and antiphospholipid antibodies), and markers or regulators of fibrinolysis (eg, D-dimer, plasminogen activator inhibitor-1, and lipoprotein[a]) should be completed. Interpretation of procoagulant factor and intrinsic anticoagulant levels should take into account the age dependence of normal values for these proteins. Among these VTE risk factors, antiphospholipid antibodies and elevated levels of homocysteine and lipoprotein(a) have also been well-demonstrated as risk factors for arterial thrombotic and ischemic events.

D. Imaging
Appropriate radiologic imaging is essential to objectively document the thrombus and to delineate the type (venous versus arterial), possible vaso-occlusion, and extent of thrombosis.

Treatment
Current guidelines for the treatment of first-episode VTE in children have been largely based on adult experience and include therapeutic anticoagulation for at least 3 months. During the period of anticoagulation, bleeding precautions should be followed, as previously described (see treatment of Idiopathic Thrombocytopenic Purpura, earlier).

Initial therapy employs continuous intravenous unfractionated heparin or subcutaneous injections of low molecular weight heparin (LMWH) for at least 7 days, monitored by anti-Xa activity level to maintain anticoagulant levels of 0.3–0.7 or 0.5–1.0 IU/mL, respectively. Subsequent extended anticoagulant therapy is given with LMWH or daily oral warfarin, the latter agent monitored by the PT to maintain an international normalized ratio (INR) of 2.0–3.0 (2.5–3.5 in the presence of an antiphospholipid antibody). During warfarin treatment, the INR should be within the therapeutic range for two consecutive days before discontinuation of heparin. Warfarin pharmacokinetics are affected by acute illness, numerous medications, and changes in diet, and require frequent monitoring. LMWH offers the advantage of infrequent need for monitoring but is far more expensive than warfarin. In cases of limb- or life-threatening VTEs, including major proximal pulmonary embolus, and in cases of progressive VTE despite therapeutic anticoagulation, thrombolytic therapy (eg, tissue-type plasminogen activator) is often warranted. A recent cohort study has indicated that initial thrombolytic therapy may also reduce the risk of the post-thrombotic syndrome (PTS) in children with veno-occlusive deep venous thrombosis of the proximal lower extremities in whom adverse prognostic biomarkers (ie, elevated factor VIII and D-dimer levels) are present at diagnosis; however, the safety and efficacy of this approach must be evaluated in a subsequent clinical trial.

Prognosis
Registries and cohort studies have suggested that recurrent VTE occurs in approximately 10% of children within 2 years. Persistent thrombosis is evident following completion of a standard therapeutic course of anticoagulation in up to 30% of children, with unclear clinical importance. At least 30% of children with deep venous thrombosis involving the extremities develop PTS, a condition of venous insufficiency of varying severity characterized by chronic skin changes, edema, and dilated collateral superficial venous formation, and often accompanied by functional limitation (pain with activities or at rest). The presence of homozygous anticoagulant deficiencies, multiple thrombophilia traits, or persistent antiphospholipid antibodies following VTE diagnosis has been associated with increased risk of recurrent VTE, leading to recommendation for extended anticoagulation in these instances. Recent evidence suggests that elevated plasma levels of factor VIII and D-dimer may be predictive of long-term post-thrombotic outcomes in children, including recurrent VTE, persistent thrombosis, and the development of PTS.

SPLENIC ABNORMALITIES

SPLENOMEGALY & HYPERSPLENISM

The differential diagnosis of splenomegaly includes the general categories of congestive splenomegaly, chronic infections, leukemia and lymphomas, hemolytic anemias, reticuloendothelioses, and storage diseases (Table 28–9).

Splenomegaly due to any cause may be associated with hypersplenism and the excessive destruction of circulating red cells, white cells, and platelets. The degree of cytopenia is variable and, when mild, requires no specific therapy. In other cases, the thrombocytopenia may cause life-threatening bleeding, particularly when the splenomegaly is secondary to portal hypertension and associated with esophageal varices or the consequence of a storage disease. In such cases, treatment with surgical splenectomy or with splenic embolization may be warranted. Although more commonly associated with acute enlargement, rupture of an enlarged spleen can be seen in more chronic conditions such as Gaucher disease.

ASPLENIA & SPLENECTOMY

Children who lack normal splenic function are at risk for sepsis, meningitis, and pneumonia due to encapsulated bacteria such as pneumococci and H influenzae. Such infections are often fulminant and fatal because of inadequate antibody production and impaired phagocytosis of circulating bacteria. Congenital asplenia is usually suspected when an infant is born with abnormalities of abdominal viscera and complex cyanotic congenital heart disease. Howell-Jolly bodies are usually present on the peripheral blood smear, and the absence of splenic tissue is confirmed by technetium radionuclide scanning. The prognosis depends on the underlying cardiac lesions, and many children die during the first few months. Prophylactic antibiotics, usually penicillin, and pneumococcal conjugate and polysaccharide vaccines are recommended.

The risk of overwhelming sepsis following surgical splenectomy is related to the child’s age and to the underlying disorder. Because the risk is highest when the procedure is performed earlier in life, splenectomy is usually postponed until after age 5 years. The risk of postsplenectomy sepsis is also greater in children with malignancies, thalassemias, and reticuloendothelioses than in children whose splenectomy is performed for ITP, hereditary spherocytosis, or trauma. Prior to splenectomy, children should be immunized against Streptococcus pneumoniae, H influenzae, and Neisseria meningitidis. Additional management should include penicillin...
prophylaxis and prompt evaluation for fever 38.8°C or above or signs of severe infection.

Children with sickle cell anemia develop functional asplenia during the first year of life, and overwhelming sepsis is the leading cause of early deaths in this disease. Prophylactic penicillin reduces the incidence of sepsis by 84%.

**TRANSFUSION MEDICINE**

**DONOR SCREENING & BLOOD PROCESSING: RISK MANAGEMENT**

Minimizing the risks of transfusion begins by asking the donor questions that will protect the recipient from transmission of infectious agents as well as other risks of transfusions. In addition, information defining high-risk groups whose behavior increases the possible transmission of HIV, hepatitis, and other diseases is provided, with the request that persons in these groups not donate blood.

Before blood components can be released for transfusion, donor blood is screened for hepatitis B surface antigen; antibodies to hepatitis B, hepatitis C, HIV-1 and HIV-2, and human T-cell lymphotropic virus (HTLV) I and II; and a serologic test for syphilis (Table 28–10). Screening donor blood for viral genome (nucleic acid amplification [NAT] testing) was mandated for HIV, HCV, and West Nile virus. NAT testing for other viruses may be added in the future, and screening for Chagas disease was accepted in 2007. Positive tests are repeated.

Upon their confirmation, the unit in question is destroyed and the donor is notified and deferred from future donations. Many of the screening tests used are very sensitive and have a high rate of false-positive results. As a result, confirmatory tests have been developed to check the initial screen-

ing results and separate the false-positives from the true-positives. Recently, bacterial culture of platelet concentrates was added to the testing paradigm.

With these approaches, the risk of an infectious complication from blood components has been minimized (see Table 28–10), with the greatest risk being post-transfusion hepatitis (see sections on hepatitis C virus and non-A, non-B, non-C hepatitis in Chapter 21). Autologous donation is recognized by some centers as a safe alternative to homologous blood. Issues of donor size make the techniques of autologous donation difficult to apply to the pediatric population.

Primary CMV infections are significant complications of blood transfusion in transplant recipients, neonates, and immunodeficient individuals. Transmission of CMV can be avoided by using seronegative donors, apheresis platelet concentrates collected by techniques ensuring low numbers of residual white cells, or red cell or platelet products leukocyte-depleted by filtering (< 5 million white blood cells per packed red cell unit or apheresis platelet concentrate equivalent).

**STORAGE & PRESERVATION OF BLOOD & BLOOD COMPONENTS**

Whole blood is routinely fractionated into packed red cells, platelets, and FFP or cryoprecipitate for most efficient use of all blood components. The storage conditions and biologic characteristics of the fractions are summarized in Table 28–11. The conditions provide the optimal environment to maintain appropriate recovery, survival, and function and are different for each blood component. For example, red cells undergo dramatic metabolic changes during their 35–42-day storage, with a decrease in 2,3-diphosphoglycerate (DPG) by day 14 of storage, a decrease in adenosine triphosphate, and a gradual loss of intracellular potassium. Fortunately, these changes are reversed readily within hours to days after the red cells are transfused. However, in certain clinical conditions, these effects may define the type of components used. For example, blood less than 7–10 days old would be preferred for exchange transfusion in neonates or replacement of red cells in persons with severe cardiopulmonary disease to ensure adequate oxygen-carrying capacity. Storage time is not an issue when administering transfusions to those with chronic anemia.

If extracellular potassium in older packed red cells may present a problem, one may use blood less than 10 days old, making packed cells out of an older unit of whole blood, or washing blood stored as packed cells. Regardless of the blood’s age, over 70% of the red cells will circulate after transfusion and approximate normal survival in the circulation. Platelets are stored at 22°C for a maximum of 5 days; criteria for 7-day storage are being developed. At the extremes of storage, there should be at least a 60% recovery, a survival time that approximates turnover of fresh autologous platelets, and normalization of the bleeding time or PFA-100 in proportion to the peak platelet count. Frozen components, red cells, FFP, and cryoprecipitate are outdated at 10 years, 1 year, and 1 year, respectively. Frozen red cells retain the same biochemical and functional characteristics as the day they were frozen. FFP contains 80% or more of all of the clotting factors of fresh plasma. Factors VIII and XIII and fibrinogen are concentrated in cryoprecipitate.

**PRETRANSFUSION TESTING**

Both the donated blood and the recipient are tested for ABO and Rh(D) antigens and for auto- or alloantibodies in the plasma. The cross-match is required on any component that contains red cells. In the major cross-match, washed donor red cells are incubated with the serum from the patient, and agglutination is detected and graded. The antiglobulin phase of the test is then performed; Coombs reagent, which will detect the presence of IgG or complement on the surface of the red cells, is added to the mixture, and agglutination is evaluated. In the presence of a negative antibody screen in the recipient, a negative immediate spin cross-match test confirms the compatibility of the blood and antiglobulin phase is not required. Further testing is required if the antibody screen or the cross-match is positive, and blood should not be given until the nature of the reactivity is delineated. An incompatible cross-match is evaluated first with a DAT or Coombs test to detect IgG or complement on the surfaces of the recipient’s red cells. The indirect antiglobulin test is also used to determine the presence of antibodies that will coat or activate complement, and additional studies are completed to define the antibody.

**TRANSFUSION PRACTICE**

**General Rules**

Several rules should be observed in administering any blood component:

1. In final preparation of the component, no solutions should be added to the bag or tubing set except for normal saline (0.9% sodium chloride for injection, USP), ABO-compatible plasma, or other specifically approved expanders. Hypotonic solutions cause hemolysis of red cells, and, if these are transfused, a severe reaction will occur. Any reconstitution should be completed by the blood bank.

2. Transfusion products should be protected from contact with any calcium-containing solution (eg, lactated Ringer); recalcification and reversal of the citrate effect will cause clotting of the blood component.

3. Blood components should not be warmed to a temperature greater than 37°C. If a component is incubated in a water bath, it should be enclosed in a watertight bag to prevent bacterial contamination of entry ports.

4. Whenever a blood bag is entered, the sterile integrity of the system is violated, and that unit should be discarded within 4 hours if left at room temperature or within 24 hours if the temperature is 4–6°C.
### Table 28-11. Characteristics of blood and blood components.

<table>
<thead>
<tr>
<th>Component</th>
<th>Storage Conditions</th>
<th>Composition and Transfusion Characteristics</th>
<th>Indications</th>
<th>Risks and Precautions</th>
<th>Administration</th>
</tr>
</thead>
<tbody>
<tr>
<td>Whole blood</td>
<td>4°C for 35 days. RBC characteristics:</td>
<td>Contains RBCs and many plasma compounds of whole blood. Leukocytes and platelets lose activity or viability after a few days under these conditions. Procoagulant clotting factors (particularly VIII and V) deteriorate rapidly during storage. Each unit has about 500 mL volume and Hct 36-40%.</td>
<td>Oxygen carrying capacity (anemia). Volume replacement for blood loss (&gt; 15-20%) or severe shock.</td>
<td>Must be ABO-identical and cross-match-compatible. Infections. Febrile or hemolytic transfusion reactions. Alloimmunization to red cell, white cell, or platelet antigens.</td>
<td>During acute blood loss, as rapidly as tolerated. In other settings, 2-4 h. 10 mL/kg will raise Hct by 5% and support volume.</td>
</tr>
<tr>
<td>Packed red cells</td>
<td>Same as for whole blood. Special rejuvenating solutions allow storage for 42 d.</td>
<td>Contains RBCs; most plasma removed in preparation. Status of leukocytes, clotting factors, and platelets same as for whole blood. Hct about 70%, volume 200-250 mL. May request tighter pack to give Hct 80-90%.</td>
<td>Oxygen carrying capacity. Acute trauma or bleeding or situations requiring intensive cardiopulmonary support (Hct &lt; 25-30%). Chronic anemia (Hct &lt; 20%).</td>
<td>Same as for whole blood.</td>
<td>May be given as patient will tolerate, based on cardiovascular status over 2-4 h. Dose of 3 mL packed RBC/kg will raise Hct by 3%. If cardiovascular status is stable, give 10 mL/kg over 2-4 h. If unstable, use smaller volume or do packed RBC exchange.</td>
</tr>
<tr>
<td>Washed or filtered red cells</td>
<td>When cells are washed, there is a 24-h outdate. Up to that time, they have the same characteristics as for packed red cells.</td>
<td>Same as for packed red cells.</td>
<td>Same as packed red cells. Depending on technique used and extent of reduction of white blood cells, washed red cells may achieve the following:</td>
<td>Same as whole blood. Removal of white cells diminishes the risk of febrile reactions. Filtration with high-efficiency white cell filters may decrease rate of alloimmunization to white cell antigens and transmission of CMV.</td>
<td>Same as for packed red cells.</td>
</tr>
<tr>
<td>Frozen red cells</td>
<td>Packed red cells frozen in 40% glycerol solution at less than -65°C. After storage for 10 y, cells retain the same biochemical characteristics, function, and capacity for survival as on the day they were frozen; when thawed, 24-h outdate.</td>
<td>Same as for packed red cells.</td>
<td>Same as packed red cells. Useful for avoiding febrile reactions, decreasing transmission of CMV, autologous blood donation, and developing an inventory of rare red cell blood groups.</td>
<td>Same as for whole blood. Risk of CMV transmission is at same level as using seronegative components.</td>
<td>Same as for packed red cells.</td>
</tr>
<tr>
<td>Fresh frozen plasma</td>
<td>Plasma from whole blood stored at less than −18°C for up to 1 y.</td>
<td>Contains &gt; 80% of all procoagulant and anticoagulant plasma proteins.</td>
<td>Replacement of plasma procoagulant and anticoagulant plasma proteins. May provide “other” factors, eg, treatment of TTP.</td>
<td>Need not be cross-matched; should be type-compatible. Volume over-load, infectious diseases, allergic reactions. Solvent detergent-treated plasma or donor-retested plasma units have decreased risk for viral transmission.</td>
<td>As rapidly as tolerated by patient, but not &gt; 4 h. Dose: 10–15 mL/kg will increase level of all clotting factors by 10–20%.</td>
</tr>
<tr>
<td>---------------------</td>
<td>----------------------------------------------------------------</td>
<td>--------------------------------------------------------------------</td>
<td>--------------------------------------------------------------------------------------------------------------------------------</td>
<td>--------------------------------------------------------------------------------------------------------------------------------</td>
<td>--------------------------------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>Cryoprecipitate</td>
<td>Produced by freezing fresh plasma to less than −65°C, then allowed to thaw 18 h at 4°C. After centrifugation, cryoprecipitable proteins are separated. May be stored at less than −18°C for up to 1 y.</td>
<td>Contains factor VIII, fibrinogen, and fibronectin at concentrations greater than those of plasma. Also contains factor XIII, VIII &gt; 80 IU/pack, fibrinogen 100–350 mg/pack.</td>
<td>Treatment of acquired or congenital deficiencies of fibrinogen. Useful in making biologic glues that contain fibrinogen. Commercial clotting factor concentrates are the treatment of choice for factor VIII deficiency and von Willebrand disease because sterilization procedures further reduce the risk of viral transmission.</td>
<td>Same as for fresh frozen plasma. ABO agglutinogens may also be concentrated and can give positive direct agglutination test if not type-specific.</td>
<td>Cryoprecipitate can be given as a rapid infusion. Dose: 1/2 pack/kg body weight will increase factor VIII level by 80–100% and fibrinogen by 200–250 mg/dL.</td>
</tr>
<tr>
<td>Platelet concentrates from whole blood donation</td>
<td>Separated from platelet-rich plasma and stored with gentle agitation at 22°C for 3–5 d. Containers currently in use are plastic and allow for gas exchange, diffusion of CO₂ helps keep pH &gt; 6, a major factor in keeping platelets viable and functional.</td>
<td>Each unit contains about 5 × 10¹⁰ platelets. Survival: Although there may be some loss with storage, 60–70% recovery should be achieved, with stored platelets able to correct platelet function test in proportion to the peak counts reached.</td>
<td>Treatment of thrombocytopenia or platelet function defects.</td>
<td>No cross-match necessary. Should be ABO type-specific. Other risks as for whole blood.</td>
<td>Can be taken during rapid transfusion or as defined by cardiovascular status, not more than 4 h. Dose: 10 mL/kg should increase platelet count by at least 50,000/μL.</td>
</tr>
<tr>
<td>Platelet concentrates by apheresis techniques</td>
<td>Same as random donor units.</td>
<td>Platelet content is equivalent to 6–10 units of random donor concentrates. Depending on technique used, these may be relatively free of leukocytes, which is important for avoiding alloimmunization.</td>
<td>As above, particularly useful in treating patients who have insufficient production and also may have a problem with alloisoimmunization.</td>
<td>Same as above.</td>
<td>As above.</td>
</tr>
<tr>
<td>Granulocytes</td>
<td>Although they may be stored stationary at 20–24°C, transfuse as soon as possible after collection.</td>
<td>Contains at least 1 × 10¹⁰ granulocytes, but also platelets and red cells. When donors given 10 mcg/kg G-CSF subcutaneously and 8 mg Decadron orally 12–15 h before collection, yield increases to &gt; 5 × 10¹⁰ granulocytes.</td>
<td>Severely neutropenic individuals (&lt; 500/μL) with poor marrow reserves and suspected bacterial or fungal infections not responding to 48–72 h of parenteral antibiotics. Also in patients with neutrophil dysfunction.</td>
<td>Same as for platelets. Pulmonary leukostasis reactions. Severe febrile reactions.</td>
<td>Given in an infusion over 2–4 h. Dose: 1 unit daily for newborns and infants, 1 × 10⁹ granulocytes per kg.</td>
</tr>
</tbody>
</table>

CMV, cytomegalovirus; DPG, diphosphoglycerate; G-CSF, granulocyte colony-stimulating factor; Hct, hematocrit; RBC, red blood cell.
5. Transfusions of products containing red cells should not exceed 4 hours. Blood components in excess of what can be infused during this time period should be stored in the blood bank until needed.

6. Before transfusion, the blood component should be inspected visually for any unusual characteristics, such as the presence of flocculent material, hemolysis, or clumping of cells, and mixed thoroughly.

7. The unit and the recipient should be identified properly.

8. The administration set includes a standard 170–260 micron filter. Under certain clinical circumstances, an additional microaggregate filter may be used to eliminate small aggregates of fibrin, white cells, and platelets that will not be removed by the standard filter.

9. The patient should be observed during the entire transfusion and especially during the first 15 minutes. Any adverse symptoms or signs should be evaluated immediately and reactions to the transfusion reported promptly to the transfusion service.

10. When cross-match–incompatible red cells or whole blood unit(s) must be given to the patient (as with autoimmune hemolytic anemia), a test dose of 10% of the total volume (not to exceed 50 mL) should be administered over 15–20 minutes; the transfusion is then stopped and the patient observed. If no adverse effects are noted, the remainder of the volume can be infused carefully.

11. Blood for exchange transfusion in the newborn period may be cross-matched with either the infant’s or the mother’s serum. If the exchange is for hemolysis, 500 mL of whole blood stored for less than 7 days will be adequate. If replacement of clotting factors is a key issue, packed red cells (7 days old) reconstituted with FFP may be considered. Based on post-transfusion platelet counts, platelet transfusion may be considered. Other problems to be anticipated are acid-base derangements, hyponatremia, hyperkalemia, hypocalcemia, hypoglycemia, hypothermia, and hypervolemia or hypovolemia.

Choice of Blood Component

Several principles should be considered when deciding on the need for blood transfusion. Indications for blood or blood components must be well defined, and the patient’s medical condition, not just the laboratory results, should be the basis for the decision. Specific deficiencies exhibited by the patient (eg, oxygen-carrying capacity, thrombocytopenia) should be treated with appropriate blood components and the use of whole blood minimized. Information about specific blood components is summarized in Table 28–11.

A. Whole Blood

Whole blood may be used in patients who require replacement of oxygen-carrying capacity and volume. More specifically, it should be considered when more than 15% of blood volume is lost. Doses vary depending on volume considerations (see Table 28–11). In acute situations, the transfusion may be completed rapidly to support blood volume.

B. Packed Red Cells

Packed red cells (which include leukocyte-poor, filtered, or frozen deglycerolized products) prepared from whole blood by centrifugal techniques are the appropriate choice for almost all patients with deficient oxygen-carrying capacity. Exact indications will be defined by the clinical setting, the severity of the anemia, the acuity of the condition, and any other factors affecting oxygen transport.

C. Platelets

The decision to transfuse platelets depends on the patient’s clinical condition, the status of plasma phase coagulation, the platelet count, the cause of the thrombocytopenia, and the functional capacity of the patient’s own platelets. In the face of decreased production and platelet counts less than 10,000–20,000/μL, the risk of severe, spontaneous bleeding is increased markedly, and—in the absence of antibody-mediated thrombocytopenia—transfusion should be considered. Under certain circumstances, especially with platelet dysfunction or treatment that inhibits the procoagulant system, transfusions at higher platelet counts may be necessary.

Transfused platelets are sequestered temporarily in the lungs and spleen before reaching their peak concentrations, 45–60 minutes after transfusion. A significant proportion of the transfused platelets never circulate but remain sequestered in the spleen. This phenomenon results in reduced recovery; only 60–70% of the transfused platelets are accounted for when peripheral platelet count increments are used as a measure of response.

In addition to cessation of bleeding, two variables indicate the effectiveness of platelet transfusions. The first is platelet recovery, as measured by the maximum number of platelets circulating in response to transfusion. The practical measure is the platelet count at 1 hour after transfusion. In the absence of immune or drastic nonimmune factors that markedly decrease platelet recovery, one would expect a 7000/μL increment for each random donor unit and a 40,000–70,000/μL increment for each single-donor apheresis unit in a large child or adolescent. For infants and small children, 10 mL/kg of platelets will increase the platelet count by at least 50,000/μL. The second variable is the survival of transfused platelets. Normally, if the recovery is great enough, transfused platelets will approach a normal half-life in the circulation. In the presence of increased platelet destruction, the life span may be shortened to a few days or a few hours. Frequent platelet transfusions may be required to maintain adequate hemostasis.

A particularly troublesome outcome in patients receiving long-term platelet transfusions is the development of a refractory state characterized by poor (< 30%) recovery or...
no response to platelet transfusion (as measured at 1 hour). Most (70–90%) of these refractory states result from the development of alloantibodies directed against HLA antigens on the platelet. Platelets have class I HLA antigens, and the antibodies are primarily against HLA A or B determinants. A smaller proportion of these alloantibodies (< 10%) may be directed against platelet-specific alloantigens. The most effective approach to prevent HLA sensitization is to use leukocyte-depleted components (< 5 million leukocytes per unit of packed red cells or per apheresis or 6–10 random donor unit concentrates). For the alloimmunized, refractory patient, the best approach is to provide HLA-matched plate-

Table 28–12. Adverse events following transfusions.

</thead>
<tbody>
<tr>
<td>Acute hemolytic transfusion reaction</td>
<td>Preformed alloantibodies (most commonly to ABO) and occasionally autoantibodies cause rapid intravascular hemolysis of transfused cells with activation of clotting (DIC), activation of inflammatory mediators, and acute renal failure.</td>
<td>Fever, chills, nausea, chest pain, back pain, pain at transfusion site, hypotension, dyspnea, oliguria, hemoglobinuria.</td>
<td>The risk of this type of reaction overall is low (1:30,000), but the mortality rate is high (up to 40%). Stop the transfusion; maintain renal output with intravenous fluids and diuretics (furosemide or mannitol); treat DIC with heparin; and institute other appropriate supportive measures.</td>
</tr>
<tr>
<td>Febrile reactions</td>
<td>Usually caused by leukoagglutinins in recipient, cytokines, or other biologically active compounds.</td>
<td>Fever. May also involve chills.</td>
<td>Supportive. Consider leukocyte-poor products for future. Risk per transfusion, 1:400–1:200.</td>
</tr>
<tr>
<td>Allergic reactions</td>
<td>Most causes not identified. In IgA-deficient individuals, reaction occurs as a result of antibodies to IgA.</td>
<td>Itching, hives, occasionally chills and fever. In severe reactions, may see signs of anaphylaxis: dyspnea, pulmonary edema.</td>
<td>Mild to moderate reactions: diphenhydramine. More severe reactions: epinephrine subcutaneously and steroids intravenously. Risk for mild to moderate allergic reactions, 1:1000. Severe anaphylactic reactions, 1:150,000.</td>
</tr>
<tr>
<td>Transfusion-related acute lung injury</td>
<td>Acute lung injury occurring within 6 h after transfusion. Two sets of factors interact to produce the syndrome. Patient factors: infection, surgery, cytokine therapy. Blood component factors: lipids, antibodies, cytokines. Two groups of factors interact during transfusion to result in lung injury indistinguishable from ARDS.</td>
<td>Tachypnea, dyspnea, hypoxia. Diffuse interstitial markings. Cardiac evaluation normal.</td>
<td>May consider younger products: packed red blood cells ≤ 2 weeks, platelets ≤ 3 days, washing components to prevent syndrome. Management: supportive care. Risk, 1:2000–1:3000 per transfusion. Current preventative procedures include avoiding donors at risk for alloimmunization: use of male-only FFP or white blood cell antibody-negative apheresis FFP or platelet products.</td>
</tr>
<tr>
<td>Dilutional coagulopathy</td>
<td>Massive blood loss and transfusion with replacement with fluids or blood components and deficient clotting factors.</td>
<td>Bleeding.</td>
<td>Replacement of clotting factors or platelets with appropriate blood components.</td>
</tr>
<tr>
<td>Bacterial contamination</td>
<td>Contamination of units results in growth of bacteria or production of clinically significant levels of endotoxin.</td>
<td>Chills, high fever, hypotension, other symptoms of sepsis or endotoxemia.</td>
<td>Stop transfusion; make aggressive attempts to identify organism; provide vigorous supportive medical care including antibiotics.</td>
</tr>
<tr>
<td>Graft-versus-host disease</td>
<td>Lymphocytes from donor transfused in an immunoincompetent host.</td>
<td>Syndrome can involve a variety of organs, usually skin, liver, gastrointestinal tract, and bone marrow.</td>
<td>Preventive management: irradiation (&gt; 1500 cGy) of cellular blood components transfused to individuals with congenital or acquired immunodeficiency syndromes, intrauterine transfusion, very premature infants, and when donors are relatives of the recipient.</td>
</tr>
<tr>
<td>Iron overload</td>
<td>There is no physiologic mechanism to excrete excess iron. Target organs include liver, heart, and endocrine organs. In patients receiving red cell transfusions over long periods of time, there is an increase in iron burden.</td>
<td>Signs and symptoms of dysfunctional organs affected by the iron.</td>
<td>Chronic administration of iron chelator such as deferoxamine.</td>

</table>
lets for transfusion. Reports have suggested that platelet cross-matching procedures using HLA-matched or unmatched donors may be helpful in identifying platelet concentrates most likely to provide an adequate response.

**D. Fresh Frozen Plasma**

The indication for FFP is replacement of plasma coagulation factors in clinical situations in which a deficiency of one or more clotting factors exists and associated bleeding manifestations are present. In some hereditary factor deficiencies, such as factor VIII deficiency or vWD, commercially prepared concentrates contain these factors in higher concentrations and, because of viral inactivation, impose less infectious risk and are more appropriate than plasma.

**E. Cryoprecipitate**

This component may be used for acquired or congenital disorders of hypofibrinogenemia or afibrinogenemia. Although cryoprecipitate is a rich source for factor VIII or vWF, commercial concentrates that contain these factors are more appropriate (see preceding section). The dose given depends on the protein to be replaced. Cryoprecipitate can be given in a rapid transfusion over 30–60 minutes.

**F. Granulocytes**

With better supportive care over the past 10 years, the need for granulocytes in neutropenic patients with severe bacterial infections has decreased. Indications still remain for severe bacterial or fungal infections unresponsive to vigorous medical therapy in either newborns or older children with bone marrow failure, or patients with neutrophil dysfunction. Newer mobilization schemes using G-CSF and steroids in donors result in granulocyte collections with at least $5 \times 10^{10}$ neutrophils. This may provide a better product for patients requiring granulocyte support.

**G. Apheresis Products and Procedures**

Apheresis equipment allows one or more blood components to be collected from a donor while the rest are returned. Apheresis platelet concentrates, which have as many platelets as 6–10 units of platelet concentrates from whole blood donations, are one example; granulocytes are another. Apheresis techniques can also be used to collect hematopoietic stem cells that have been mobilized into the blood by cytokines (G-CSF or GM-CSF) given alone or after chemotherapy. These stem cells are used for allogeneic or autologous bone marrow transplantation. Blood cell separators can be used for the collection of single-source plasma or removal of a blood component that is causing disease. Examples include red cell exchange in sickle cell disease and plasmapheresis in Goodpasture syndrome or in Guillain-Barré syndrome.

**Adverse Effects**

The noninfectious complications of blood transfusions are outlined in Table 28–12. Most complications present a significant risk to the recipient.

Each year approximately 150 of every 1 million children younger than age 20 years are diagnosed with cancer. For children between the ages of 1 and 20 years, cancer is the fourth leading cause of death, behind unintentional injuries, homicides, and suicides. However, combined-modality therapy, including surgery, chemotherapy, and radiation therapy, has improved survival dramatically, such that the overall 5-year survival rate of pediatric malignancies is now greater than 75%. It is estimated that by the year 2020, 1 in 600 adults will be a survivor of childhood cancer.

Because pediatric malignancies are rare, cooperative clinical trials have become the mainstay of treatment planning and therapeutic advances. The Children’s Oncology Group (COG), representing the amalgamation of four prior pediatric cooperative groups (Children’s Cancer Group, Pediatric Oncology Group, Intergroup Rhabdomyosarcoma Study Group, and the National Wilms Tumor Study Group), offers current therapeutic protocols and strives to answer important treatment questions. A child or adolescent newly diagnosed with cancer should be enrolled in a cooperative clinical trial whenever possible. Because many protocols are associated with significant toxicities, morbidity, and potential mortality, treatment of children with cancer should be supervised by a pediatric oncologist familiar with the hazards of treatment, preferably at a multidisciplinary pediatric cancer center.

Advances in molecular genetics, cell biology, and tumor immunology have contributed and are crucial to the continued understanding of pediatric malignancies and their treatment. Continued research into the biology of tumors will lead to the identification of targeted therapy for specific tumor types with, it is hoped, fewer systemic effects.

Research in supportive care areas, such as prevention and management of infection, pain, and emesis, has improved the survival and quality of life for children undergoing cancer treatment. Long-term studies of childhood cancer survivors are yielding information that provides a rationale for modifying future treatment regimens to decrease morbidity. A guide for caring for childhood cancer survivors is now available to medical providers as well as families and details suggested examinations and late effects by type of chemotherapy received.

MAJOR PEDIATRIC NEOPLASTIC DISEASES

ACUTE LYMPHOBLASTIC LEUKEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Bone marrow aspirate or biopsy specimen shows more than 25% lymphoblasts.
- Pallor, petechiae, purpura (50%), bone pain (25%).
- Hepatosplenomegaly (60%), lymphadenopathy (50%).
- Single or multiple cytopenias: neutropenia, thrombocytopenia, anemia (99%).
- Leukopenia (15%) or leukocytosis (50%), often with lymphoblasts identifiable on blood smear.
- Diagnosis confirmed by bone marrow examination.

General Considerations

Acute lymphoblastic leukemia (ALL) is the most common malignancy of childhood, accounting for about 25% of all cancer diagnoses in patients younger than age 15 years. The worldwide incidence of ALL is about 1:25,000 children per year, including 3000 children per year in the United States. The peak age at onset is 4 years; 85% of patients are diagnosed...
between ages 2 and 10 years. Children with Down syndrome have a 14-fold increase in the overall rate of leukemia.

ALL results from uncontrolled proliferation of immature lymphocytes. Its cause is unknown, and genetic factors may play a role. Leukemia is defined by the presence of more than 25% malignant hematopoietic cells (blasts) on bone marrow aspirate. Leukemic blasts from the majority of cases of childhood ALL have an antigen on the cell surface called the common ALL antigen (CALLA). These blasts derive from B-cell precursors early in their development, called B-precursor ALL. Less commonly, lymphoblasts are of T-cell origin or of mature B-cell origin. Over 70% of children receiving aggressive combination chemotherapy and early presymptomatic treatment to the central nervous system (CNS) are now cured of ALL.

Clinical Findings

A. Symptoms and Signs

Presenting complaints of patients with ALL include those related to decreased bone marrow production of red blood cells (RBCs), white blood cells (WBCs), or platelets and to leukemic infiltration of extramedullary (outside bone marrow) sites. Intermittent fevers are common, as a result of either cytokines induced by the leukemia itself or infections secondary to leukopenia. Many patients present due to bruising or pallor. About 25% of patients experience bone pain, especially in the pelvis, vertebral bodies, and legs. Physical examination at diagnosis ranges from virtually normal to highly abnormal. Signs related to bone marrow infiltration by leukemia include pallor, petechiae, and purpura. Hepatomegaly or splenomegaly occurs in over 60% of patients. Lymphadenopathy is common, either localized or generalized to cervical, axillary, and inguinal regions. The tests may occasionally be unilaterally or bilaterally enlarged secondary to leukemic infiltration. Superior vena cava syndrome is caused by mediastinal adenopathy compressing the superior vena cava. A prominent venous pattern develops over the upper chest from collateral vein enlargement. The neck may feel full from venous engorgement. The face may appear plethoric, and the periorbital area may be edematous.

A mediastinal mass can cause tachypnea, orthopnea, and respiratory distress. Leukemic infiltration of cranial nerves may cause cranial nerve palsies with mild nuchal rigidity. The optic fundi may show exudates of leukemic infiltration and hemorrhage from thrombocytopenia. Anemia can cause a flow murmur, tachycardia, and, rarely, congestive heart failure.

B. Laboratory Findings

A complete blood count (CBC) with differential is the most useful initial test because 95% of patients with ALL have a decrease in at least one cell type (single cytopenia): neutropenia, thrombocytopenia, or anemia. Most patients have decreases in at least two blood cell lines. The WBC count is low or normal (= 10,000/μL) in 50% of patients, but the differential shows neutropenia (absolute neutrophil count < 1000/μL) along with a small percentage of blasts amid normal lymphocytes. In 30% of patients the WBC count is between 10,000 and 50,000/μL; in 20% of patients it is over 50,000/μL, occasionally higher than 300,000/μL. Blasts are usually readily identifiable on peripheral blood smears from patients with elevated WBC counts. Peripheral blood smears also show abnormalities in RBCs, such as teardrops. Most patients with ALL have decreased platelet counts (< 150,000/μL) and decreased hemoglobin (< 11 g/dL) at diagnosis. In approximately 1% of patients diagnosed with ALL, CBCs and peripheral blood smears are entirely normal but patients have bone pain that leads to bone marrow examination. Serum chemistries, particularly uric acid and lactate dehydrogenase (LDH), are often elevated at diagnosis as a result of cell breakdown.

The diagnosis of ALL is made by bone marrow examination, which shows a homogeneous infiltration of leukemic blasts replacing normal marrow elements. The morphology of blasts on bone marrow aspirate can usually distinguish ALL from acute myeloid leukemia (AML). Lymphoblasts are typically small, with cell diameters of approximately two erythrocytes. Lymphoblasts have scant cytoplasm, usually without granules. The nucleus typically contains no nucleoli or one small, indistinct nucleolus. Immunophenotyping of ALL blasts by flow cytometry helps distinguish precursor B-cell ALL from T-cell ALL or AML. Histochemical stains specific for myeloblastic and monoblastic leukemias (myeloperoxidase and nonspecific esterase) distinguish ALL from AML. About 5% of patients present with CNS leukemia, which is defined as a cerebrospinal fluid (CSF) WBC count greater than 5/μL with blasts present on cytocentrifuged specimen.

C. Imaging

Chest radiograph may show mediastinal widening or an anterior mediastinal mass and tracheal compression secondary to lymphadenopathy or thymic infiltration, especially in T-cell ALL. Abdominal ultrasound may show kidney enlargement from leukemic infiltration or uric acid nephropathy as well as intra-abdominal adenopathy. Plain radiographs of the long bones and spine may show demineralization, periosteal elevation, growth arrest lines, or compression of vertebral bodies.

Differential Diagnosis

The differential diagnosis, based on the history and physical examination, includes chronic infections by Epstein-Barr virus (EBV) and cytomegalovirus (CMV), causing lymphadenopathy, hepatosplenomegaly, fevers, and anemia. Prominent petechiae and purpura suggest a diagnosis of immune thrombocytopenic purpura. Significant pallor could be caused by transient erythroblastopenia of childhood, autoimmune hemolytic anemias, or aplastic anemia. Fevers and joint pains, with or without hepatosplenomegaly and lymphade-
nopathy, suggest juvenile rheumatoid arthritis (JRA). The diagnosis of leukemia usually becomes straightforward once the CBC reveals multiple cytopenias and leukemic blasts. Serum LDH levels may help distinguish JRA from leukemia, as the LDH is usually normal in JRA. An elevated WBC count with lymphocytosis is typical of pertussis; however, in pertussis the lymphocytes are mature, and neutropenia is rarely associated.

### Treatment

#### A. Specific Therapy

Intensity of treatment is determined by specific prognostic features present at diagnosis, the patient’s response to therapy, and specific biologic features of the leukemia cells. The majority of patients with ALL are enrolled in clinical trials designed by clinical groups and approved by the National Cancer Institute; the largest group is COG. The first month of therapy consists of induction, at the end of which over 95% of patients exhibit remission on bone marrow aspirations by morphology. The drugs most commonly used in induction include oral prednisone or dexamethasone, intravenous vincristine and daunorubicin, intramuscular asparaginase, and intrathecal methotrexate. For T-cell ALL, intravenous cyclophosphamide may be added during induction.

Consolidation is the second phase of treatment, during which intrathecal chemotherapy along with continued systemic therapy and sometimes cranial radiation therapy are given to kill lymphoblasts “hiding” in the meninges. Several months of intensive chemotherapy follows consolidation. This intensification has led to improved survival in pediatric ALL.

Maintenance therapy can include daily oral mercaptopurine, weekly oral methotrexate, and, often, monthly pulses of intravenous vincristine and oral prednisone or dexamethasone. Intrathecal chemotherapy, either with methotrexate alone or combined with cytarabine and hydrocortisone, is usually given every 2–3 months.

These drugs have significant potential side effects. Patients need to be monitored closely to prevent drug toxicities and to ensure early treatment of complications. The duration of treatment ranges between 2.2 years for girls and 3.2 years for boys in COG trials. Treatment for ALL is tailored to prognostic, or risk, groups. A child aged 1–9 years with a WBC count below 50,000/μL at diagnosis and without poor biologic features [t(9;22) or t(4;11)] is considered to be at “standard risk” and receives less intensive therapy than a “high-risk” patient who has a WBC count at diagnosis over 50,000/μL or is older than age 10 years. Also important is the patient’s response to treatment determined by minimal residual disease (MRD) monitoring. This risk-adapted treatment approach has significantly increased the cure rate among patients with less favorable prognostic features while minimizing treatment-related toxicities in those with favorable features. Bone marrow relapse is usually heralded by an abnormal CBC, either during treatment or following completion of therapy.

The CNS and testes are sanctuary sites of extramedullary leukemia. Currently, about one third of all ALL relapses are isolated to these sanctuary sites. Systemic chemotherapy does not penetrate these tissues as well as it penetrates other organs. Thus, presymptomatic intrathecal chemotherapy is a critical part of ALL treatment, without which many more relapses would occur in the CNS, with or without bone marrow relapse. The majority of isolated CNS relapses are diagnosed in an asymptomatic child at the time of routine intrathecal injection, when CSF cell count and differential shows an elevated WBC with leukemic blasts. Occasionally, symptoms of CNS relapse develop: headache, nausea and vomiting, irritability, nuchal rigidity, photophobia, and cranial nerve palsies. Currently, testicular relapse occurs in less than 5% of boys. The presentation of testicular relapse is usually unilateral painless testicular enlargement, without a distinct mass. Routine follow-up of boys both on and off treatment includes physical examination of the testes.

Bone marrow transplantation, now called hematopoietic stem cell transplantation (HSCT), is rarely used as initial treatment for ALL, because most patients are cured with chemotherapy alone. Patients whose blasts contain certain chromosomal abnormalities, such as t(9;22) or hypodiploidy (<44 chromosomes), and patients with a very slow response to therapy may have a better cure rate with early HSCT from a human leukocyte antigen (HLA)-DR–matched sibling donor, or perhaps a matched unrelated donor, than with intensive chemotherapy alone. HSCT cures about 50% of patients who relapse, provided that a second remission is achieved with chemotherapy before transplant. Children who relapse more than 1 year after completion of chemotherapy (late relapse) may be cured with intensive chemotherapy without HSCT.

Several new biologic agents, including tyrosine kinase inhibitors and immunotoxins, are currently in various stages of research and development. Some of these therapies may prove relevant for future treatment of poor risk or relapsed ALL.

#### B. Supportive Care

Tumor lysis syndrome should be anticipated when treatment is started. Alkalization of urine with intravenous sodium bicarbonate, maintaining brisk urine output, and treating with oral allopurinol are appropriate steps in managing tumor lysis syndrome. Serum levels of potassium, phosphorus, and uric acid should be monitored. If superior vena caval or superior mediastinal syndrome is present, general anesthesia is contraindicated temporarily. If hyperleukocytosis (WBC count > 100,000/μL) is accompanied by hyperviscosity and mental status changes, leukopheresis may be indicated to rapidly reduce the number of circulating blasts and minimize the potential thrombotic or hemorrhagic CNS complications. Throughout the course of treatment, all transfused blood and platelet products should be irradiated to prevent graft-versus-host disease from the transfused lymphocytes. Whenever possible, blood products should be
leukodepleted to minimize CMV transmission, transfusion reactions, and sensitization to platelets.

Due to the immunocompromised state of the patient with ALL, bacterial, fungal, and viral infections are serious and can be life-threatening or fatal. During the course of treatment, fever (temperature = 38.3°C) and neutropenia (absolute neutrophil count < 500/μL) require prompt assessment, blood cultures from each lumen of a central line, and prompt treatment with empiric broad-spectrum antibiotics. Patients receiving ALL treatment must receive prophylaxis against Pneumocystis jiroveci (formerly Pneumocystis carinii). Trimethoprim–sulfamethoxazole given twice each day on 2 or 3 consecutive days per week is the drug of choice. Patients nonimmune to varicella are at risk for very serious—even fatal—infection. Such patients should receive varicella-zoster immune globulin (VZIG) within 72 hours after exposure and treatment with intravenous acyclovir for active infection.

#### Prognosis

Cure rates depend on specific prognostic features present at diagnosis, biologic features of the leukemic blast, and the response to therapy. Two of the most important features are WBC count and age. Children aged 1–9 years whose diagnostic WBC count is less than 50,000/μL have a higher rate of cure than other patients (~85% event-free survival for these children). The rapidity of response to induction treatment has prognostic significance as well, reflecting leukemic blast sensitivity to chemotherapy. Patients are categorized as rapid early responders (RERs) or slow early responders (SERs) based on the percentage of blasts present in bone marrow aspirates within 7–14 days after induction begins. More intensive treatment regimens are given to SERs than RERs to increase their chance of cure.

Certain chromosomal abnormalities present in the leukemic blasts at diagnosis influence prognosis. Patients with t(9;22) generally have a very poor chance of cure even with intensive chemotherapy. Likewise, infants younger than age 6 months with t(4;11) have a poor chance of cure with conventional chemotherapy. In contrast, patients whose blasts are hyperdiploid (containing > 50 chromosomes instead of the normal 46) with trisomies of chromosomes 4, 10, and 17, and patients whose blasts have a t(12;21) and TEL-AML1 rearrangement have a greater chance of cure, approaching 90% survival, than do children without these characteristics.

Techniques based on leukemic blast immunophenotyping or immunoglobulin rearrangements have been developed to detect residual lymphoblasts in bone marrow (MRD), at the end of induction and during remission. Many groups have shown that even low levels of MRD predict an inferior outcome. In the current COG clinical trials, patients with levels of MRD above 0.1% at the end of remission induction will receive intensified therapy, in an attempt to improve their outcome.

### ACUTE MYELOID LEUKEMIA

#### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Bone marrow aspirate or biopsy shows 20% or more leukemic blasts.
- Fatigue, bleeding, or infection.
- Adenopathy, hepatosplenomegaly, skin nodules (M4 and M5 subtypes).
- Cytopenias: neutropenia (69%), anemia (44%), thrombocytopenia (33%).

#### General Considerations

Approximately 500 new cases of acute myeloid leukemia (AML) occur per year in children and adolescents in the United States. Although AML accounts for only 25% of all leukemias in this age group, it is responsible for at least one third of deaths from leukemia in children and teenagers. Congenital conditions associated with an increased risk of AML include Diamond-Blackfan anemia; neurofibromatosis; Down syndrome; Wiskott-Aldrich, Costmann, and Li-Fraumeni syndromes; as well as chromosomal instability syndromes such as Fanconi anemia. Acquired risk factors include exposure to ionizing radiation, cytotoxic chemotherapeutic agents, and benzenes. However, the vast majority of patients have no identifiable risk factors. Historically, the diagnosis of AML was based almost exclusively on morphology and immunohistochemical staining of the leukemic cells. AML has eight subtypes (M0–M7) according to the French-American-British (FAB) classification (Table 29–1). Immunophenotypic, cytogenetic, and molecular analyses are increasingly important in confirming the diagnosis of AML and subclassifying it into biologically distinct subtypes that have therapeutic and prognostic implications. Cytogenetic clonal abnormalities occur in 80% of patients with AML and are often predictive of outcome.

Aggressive induction therapy currently results in a 75–85% complete remission rate. However, long-term survival has improved only modestly to approximately 50%, despite
the availability of several effective agents, improvements in supportive care, and increasingly intensive therapies.

### Clinical Findings

The clinical manifestations of AML commonly include anemia (44%), thrombocytopenia (33%), and neutropenia (69%). Symptoms may be few and innocuous or may be life-threatening. The median hemoglobin value at diagnosis is 7 g/dL, and platelets usually number fewer than 50,000/μL. Frequently the absolute neutrophil count is under 1000/μL, although the total WBC count is over 100,000/μL in 25% of patients at diagnosis.

Hyperleukocytosis may be associated with life-threatening complications. Venous stasis and sludging of blasts in small vessels cause hypoxia, hemorrhage, and infarction, most notably in the lung and CNS. This clinical picture is a medical emergency requiring rapid intervention, such as leukopheresis, to decrease the leukocyte count. CNS leukemia is present in 5–15% of patients at diagnosis, a higher rate of initial involvement than in ALL. Certain subtypes, such as M4 and M5, have a higher likelihood of meningeal infiltration than do other subtypes. Additionally, clinically significant coagulopathy may be present at diagnosis in patients with M3, M4, or M5 subtypes. This problem manifests as bleeding or an abnormal disseminated intravascular coagulation screen and should be at least partially corrected prior to initiation of treatment, which may transiently exacerbate the coagulopathy.

### Treatment

#### A. Specific Therapy

AML is less responsive to treatment than ALL and requires more intensive chemotherapy. Toxocities from therapy are common and likely to be life-threatening; therefore, treatment should be undertaken only at a tertiary pediatric oncology center.

Current AML protocols rely on intensive administration of anthracyclines, cytarabine, and etoposide for induction of remission. After remission is obtained patients who have a matched sibling donor undergo allogeneic HSCT while those without an appropriate related donor are treated with additional cycles of aggressive chemotherapy for a total of 6–9 months. Inv16 and t(8;21) may herald a more responsive subtype of AML. In patients with a rapid response to induction, intensive chemotherapy alone may be curative. Trials with risk grouping are ongoing as more is understood about the varying biologic factors.

The biologic heterogeneity of AML is becoming increasingly important therapeutically. The M3 subtype, associated with t(15;17) demonstrated either cytogenetically or molecularly, is currently treated with all trans-retinoic acid in addition to chemotherapy with high-dose cytarabine and daunorubicin. All trans-retinoic acid leads to differentiation of promyelocytic leukemia cells and can induce remission, but cure requires conventional chemotherapy as well. The use of arsenic trioxide has also been investigated in the treatment of

CNS, central nervous system; FAB, French-American-British classification.
this subtype of AML with favorable results. This subtype has an increased event-free survival over other AML subtypes.

Another biologically distinct subtype of AML occurs in children with Down syndrome, M7, or megakaryocytic AML. Using less intensive treatment, remission induction rate and overall survival of these children are dramatically superior to non-Down syndrome children with AML. It is important that children with Down syndrome receive appropriate treatment specifically designed to be less intensive.

Biologic agents and new chemotherapeutic agents are increasingly being studied in the treatment of AML. The development and early success of antibody-targeted cytotoxic agents such as gemtuzumab ozogamicin (Mylotarg, a humanized anti-CD33 monoclonal antibody conjugated with calicheamicin) are encouraging steps in the quest for therapeutic agents that result in higher survival rates. Use of this agent as intensive chemotherapy for AML is now being evaluated in a randomized trial. Clofarabine, a newer nucleoside analogue, also has activity in AML and is currently undergoing trials in relapsed and refractory patients.

B. Supportive Care

Tumor lysis syndrome rarely occurs during induction treatment of AML. Nevertheless, when the diagnostic WBC cell count is greater than 100,000/μL or significant adenopathy or organomegaly is present, one should alkalinate urine with intravenous sodium bicarbonate, maintain brisk urine output, and follow potassium, uric acid, and phosphorous lab values closely. Hyperleukocytosis (WBC > 100,000/μL) is a medical emergency and, in a symptomatic patient, requires rapid intervention such as leukopheresis to rapidly decrease the number of circulating blasts and thereby decrease hyper-viscosity. Delaying transfusion of packed RBCs until the WBC can be decreased to below 100,000/μL avoids exacerbating hyperviscosity. It is also important to correct the coagulopathy commonly associated with M3, M4, or M5 subtypes prior to beginning induction chemotherapy. As with the treatment of ALL, all blood products should be irradiated and leukodepleted; Pneumocystis prophylaxis must be administered during treatment and for several weeks afterward; and patients not immune to varicella must receive VZIG within 72 hours of exposure and prompt treatment with intravenous acyclovir for active infection.

Onset of fever (temperature ≥ 38.3°C) or chills associated with neutropenia requires prompt assessment, blood cultures from each lumen of a central venous line, other cultures such as throat or urine as appropriate, and prompt initiation of broad-spectrum intravenous antibiotics. Infections in this population of patients can rapidly become life-threatening. Because of the high incidence of invasive fungal infections, there should be a low threshold for initiating antifungal therapy. Filgrastim (granulocyte colony-stimulating factor) may be used to stimulate granulocyte recovery during the treatment of AML and results in shorter periods of neutropenia and hospitalization. It must be stressed that the supportive care for this group of patients is as important as the leukemia-directed therapy and that this treatment should be carried out only at a tertiary pediatric cancer center.

Prognosis

Published results from various centers show a 50–60% survival rate at 5 years following first remission for patients who do not have matched sibling hematopoietic stem cell donors. Patients with matched sibling donors fare slightly better, with 5-year survival rates of 60–70% after allogeneic HSCT.

As treatment becomes more sophisticated, outcome is increasingly related to the subtype of AML. Currently, AML in patients with t(8;21), t(15;17), inv 16, or Down syndrome has the most favorable prognosis, with 65–75% long-term survival using modern treatments, including chemotherapy alone. The least favorable outcome occurs in AML patients with monosomy 7 or 5, 7q, 5q–, or 11q23 cytogenetic abnormalities.

MYELOPROLIFERATIVE DISEASES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Leukocytosis with predominance of immature cells.
- Often indolent course.
- Fever, bone pain, respiratory symptoms.
- Hepatosplenomegaly.

Myeloproliferative diseases in children are relatively rare. They are characterized by ineffective hematopoiesis that results in excessive peripheral blood counts. The three most important types are chronic myelogenous leukemia (CML), which accounts for less than 5% of the childhood leukemias, transient myeloproliferative disorder in children with Down syndrome, and juvenile myelomonocytic leukemia (Table 29–2).

CML, chronic myelogenous leukemia; DS, Down syndrome; JMML, juvenile myelomonocytic leukemia; TMD, transient myeloproliferative disorder.

### 1. Chronic Myelogenous Leukemia

#### General Considerations

CML with translocation of chromosomes 9 and 22 (the Philadelphia chromosome, Ph⁺) is identical to adult Ph⁺CML. Translocation 9;22 results in the fusion of the BCR gene on chromosome 22 and the ABL gene on chromosome 9. The resulting fusion protein is a constitutively active tyrosine kinase that interacts with a variety of effector proteins and allows for deregulated cellular proliferation, decreased adherence of cells to the bone marrow extracellular matrix, and resistance to apoptosis. The disease usually progresses within 3 years to an accelerated phase and then to a blast crisis. It is generally accepted that Ph⁺ cells have an increased susceptibility to the acquisition of additional molecular changes that lead to the accelerated and blast phases of disease.

#### Clinical Findings

 Patients with CML may present with nonspecific complaints similar to those of acute leukemia, including bone pain, fever, night sweats, and fatigue. However, patients can also be asymptomatic. Patients with a total WBC count of more than 100,000/μL may have symptoms of leukostasis, such as dyspnea, priapism, or neurologic abnormalities. Physical findings may include fever, pallor, ecchymoses, and hepatosplenomegaly. Anemia, thrombocytosis, and leukocytosis are frequent laboratory findings. The peripheral smear is usually diagnostic, with a characteristic predominance of myeloid cells in all stages of maturation and relatively few blasts.

#### Treatment & Prognosis

Historically, hydroxyurea or busulfan has been used to reduce or eliminate Ph⁺ cells. However, HSCT is the only consistently curative intervention. Reported survival rates for patients younger than age 20 years transplanted in the chronic phase from matched related donors are 70–80%. Unrelated stem cell transplants result in survival rates of 50–65%.

The understanding of the molecular mechanisms involved in the pathogenesis of CML has led to the rational design of molecularly targeted therapy. Imatinib mesylate (Gleevec) is a tyrosine kinase inhibitor that has had dramatic success in the treatment of CML, with most adults and children achieving cytogenetic remission. The durability of the remission for children is unclear but is now the accepted upfront therapy. However, some patients are resistant to imatinib, and its role in the long-term management of children with CML awaits further studies.

### 2. Transient Myeloproliferative Disorder

Transient myeloproliferative disorder is unique to patients with trisomy 21 or mosaicism for trisomy 21. It is characterized by uncontrolled proliferation of blasts, usually of megakaryocytic origin, during early infancy and spontaneous resolution. The pathogenesis of this process is not well understood, although mutations in the GATA1 gene have recently been implicated as initial events.

Although the true incidence is unknown, it is estimated to occur in up to 10% of patients with Down syndrome. Despite the fact that the process usually resolves by 3 months of age, organ infiltration may cause significant morbidity and mortality.

Patients can present with hydrops fetalis, pericardial or pleural effusions, or hepatic fibrosis. More frequently, they are asymptomatic or only minimally ill. Therefore, treatment is primarily supportive. Patients without symptoms are not treated, and those with organ dysfunction receive low doses of chemotherapy or leukapheresis (or both) to reduce peripheral blood blast counts. Although patients with transient myeloproliferative disorder have apparent resolution of the process, approximately 30% go on to develop acute megakaryoblastic leukemia (AML M7) within 3 years.
3. Juvenile Myelomonocytic Leukemia

Juvenile myelomonocytic leukemia (JMML), accounts for approximately one third of the myelodysplastic and myelo proliferative disorders in childhood. Patients with neurofibromatosis type 1 (NF-1) are at higher risk of JMML than the general population. It typically occurs in infants and very young children and is occasionally associated with monosomy 7 or a deletion of the long arm of chromosome 7.

Patients with JMML present similarly to those with other hematopoietic malignancies, with lymphadenopathy, hepatosplenomegaly, skin rash, or respiratory symptoms. Patients may have stigmata of NF-1 with neurofibromas or café-au-lait spots. Laboratory findings include anemia, thrombocytopenia, leukocytosis with monocytosis, and elevated fetal hemoglobin.

The results of chemotherapy for children with JMML have been disappointing, with estimated survival rates of less than 30%. Approximately 40–45% of patients are projected to survive long term using HSCT, although optimizing conditioning regimens and donor selection may improve these results.

BRAIN TUMORS

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Classic triad: morning headache, vomiting, and papilledema.
- Increasing head circumference, cranial nerve palsies, dysarthria, ataxia, hemiplegia, papilledema, hyperreflexia, macrocephaly, cracked pot sign.

**Clinical Findings**

**A. Symptoms and Signs**

Clinical findings at presentation vary depending on the child’s age and the tumor’s location. Children younger than age 2 years more commonly have infratentorial tumors. Children with such tumors usually present with nonspecific symptoms such as vomiting, unsteadiness, lethargy, and irritability. Signs may be surprisingly few or may include macrocephaly, ataxia,
hyperreflexia, and cranial nerve palsies. Because the head can expand in young children, papilledema is often absent. Measuring head circumference and observing gait are essential in evaluating a child for possible brain tumor. Eye findings and apparent visual disturbances such as difficulty tracking can occur in association with optic pathway tumors such as optic glioma. Optic glioma occurring in a young child is often associated with neurofibromatosis.

Older children more commonly have supratentorial tumors, which are associated with headache, visual symptoms, seizures, and focal neurologic deficits. Initial presenting features are often nonspecific. School failure and personality changes are common. Vaguely described visual disturbance is often present, but the child must be directly asked. Headaches are common, but they often will not be predominantly in the morning. The headaches may be confused with migraine.

Older children with infratentorial tumors characteristically present with symptoms and signs of hydrocephalus, which include progressively worsening morning headache and vomiting, gait unsteadiness, double vision, and papilledema. Cerebellar astrocytomas enlarge slowly, and symptoms may worsen over several months. Morning vomiting may be the only symptom of posterior fossa ependymomas, which originate in the floor of the fourth ventricle near the vomiting center. Children with brainstem tumors may present with facial and extraocular muscle palsies, ataxia, and hemiparesis; hydrocephalus occurs in approximately 25% of these patients at diagnosis.

B. Imaging and Staging

In addition to the tumor biopsy, neuraxis imaging studies are obtained to determine whether dissemination has occurred. It is unusual for brain tumors in children and adolescents to disseminate outside the CNS.

Magnetic resonance imaging (MRI) has become the preferred diagnostic study for pediatric brain tumors. MRI provides better definition of the tumor and delineates indolent gliomas that may not be seen on computed tomography (CT) scan. In contrast, a CT scan can be done in less than 10 minutes—as opposed to the 30 minutes required for an MRI scan—and is still useful if an urgent diagnostic study is necessary or to detect calcification of a tumor. Both scans are generally done with and without contrast enhancement. Contrast enhances regions where the blood-brain barrier is disrupted. Postoperative scans to document the extent of tumor resection should be obtained within 48 hours after surgery to avoid postsurgical enhancement.

Imaging of the entire neuraxis and CSF cytologic examination should be part of the diagnostic evaluation for patients with tumors such as medulloblastoma, ependymoma, and pineal region tumors. Diagnosis of neuraxis drop metastases (tumor spread along the neuraxis) can be accomplished by gadolinium-enhanced MRI incorporating sagittal and axial views. MRI of the spine should be obtained preoperatively in all children with midline tumors of the fourth ventricle or cerebellum. A CSF sample should be obtained during the diagnostic surgery. Lumbar CSF is preferred over ventricular CSF for cytologic examination. Levels of biomarkers in the blood and CSF, such as human chorionic gonadotropin and α-fetoprotein, may be helpful at diagnosis and in follow-up. Both human chorionic gonadotropin and α-fetoprotein should be obtained from the blood preoperatively for all pineal and suprasellar tumors.

The neurosurgeon should discuss staging and sample collection with an oncologist before surgery in a child newly presenting with a scan suggestive of brain tumor.

C. Classification

About 50% of the common pediatric brain tumors occur above the tentorium and 50% in the posterior fossa. In the very young child, posterior fossa tumors are more common. Most childhood brain tumors can be divided into two categories according to the cell of origin: (1) glial tumors, such as astrocytomas and ependymomas, or (2) nonglial tumors, such as medulloblastoma and other primitive neuroectodermal tumors. Some tumors contain both glial and neural elements (eg, ganglioglioma). A group of less common CNS tumors does not fit into either category (ie, craniopharyngiomas, germ cell tumors, choroid plexus tumors, and meningiomas).

Low-grade and high-grade tumors are found in most categories. Table 29–3 lists the locations and frequencies of the common pediatric brain tumors.

Astrocytoma is the most common brain tumor of childhood. Most are juvenile pilocytic astrocytoma (WHO grade I) found in the posterior fossa with a bland cellular morphol-

Medulloblastoma and related primitive neuroectodermal tumors are the most common high-grade brain tumors in children. These tumors usually occur in the first decade of life, with a peak incidence between ages 5 and 10 years and a female-to-male ratio of 2.1:1.3. The tumors typically arise in the midline cerebellar vermis, with variable extension into the fourth ventricle. Neuraxis dissemination at diagnosis affects from 10–46% of patients. Prognostic factors are outlined in Table 29–4.

Brainstem tumors are third in frequency of occurrence in children. They are frequently of astrocytic origin and often are high-grade. Children with tumors that diffusely infiltrate the brainstem and involve primarily the pons have a long-term survival rate of less than 15%. Brainstem tumors that occur above or below the pons and grow in an eccentric or cystic manner have a somewhat better outcome. Exophytic tumors in this location may be amenable to surgery. Generally, brainstem tumors are treated without a tissue diagnosis.

Other brain tumors such as ependymomas, germ cell tumors, choroid plexus tumors, and craniopharyngiomas are less common, and each is associated with unique diagnostic and therapeutic challenges.

### Treatment

#### A. Supportive Care

Dexamethasone should be started prior to initial surgery (0.5–1.0 mg/kg initially, then 0.25–0.5 mg/kg/d in four divided doses). Anticonvulsants (usually phenytoin, 4–8 mg/kg/d) should be started if the child has had a seizure or if the surgical approach is likely to induce seizures. Because postoperative treatment of young children with high-grade brain tumors incorporates increasingly more intensive systemic chemotherapy, consideration should also be given to the use of prophylaxis for prevention of oral candidiasis and *Pneumocystis* infection. Dexamethasone and phenytoin potentially reduce the effectiveness of chemotherapy and should be discontinued as soon after surgery as possible.

Optimum care for the pediatric patient with a brain tumor requires a multidisciplinary team including subspecialists in pediatric neurosurgery, neurooncology, neurology, endocrinology, neuropsychology, radiation therapy, and rehabilitation medicine, as well as highly specialized nurses, social workers, and staff in physical therapy, occupational therapy, and speech and language science.

#### B. Specific Therapy

The goal of treatment is to eradicate the tumor with the least short- and long-term morbidity. Long-term neuropsychological morbidity becomes an especially important issue related to deficits caused by the tumor itself and the sequelae of treatment. Meticulous surgical removal of as much tumor as possible is generally the preferred initial approach. Technologic advances in the operating microscope, the ultrasonic tissue aspirator, and the CO₂ laser (which is less commonly used in pediatric brain tumor surgery); the accuracy of computerized stereotactic resection; and the availability of intraoperative monitoring techniques such as evoked potentials and electrocorticography have increased the feasibility and safety of surgical resection of many pediatric brain tumors. Second-look surgery after chemotherapy is increasingly being used when tumors are incompletely resected at initial surgery.

Radiation therapy for pediatric brain tumors is in a state of evolution. For tumors with a high probability of neuraxis dissemination (eg, medulloblastoma), craniospinal irradiation is still standard therapy in children older than age 3 years. In others (eg, ependymoma), craniospinal irradiation has been abandoned because neuraxis dissemination at first relapse is rare. Approaches to the delivery of radiation to minimize the adverse effects on normal brain tissue are being explored and include stereotactic irradiation and the use of three-dimensional treatment planning.

Chemotherapy is effective in treating low-grade and malignant astrocytomas and medulloblastomas. A series of brain tumor protocols for children younger than age 3 years involved administering intensive chemotherapy after tumor resection and delaying or omitting radiation therapy. The results of these trials have generally been disappointing but have taught valuable lessons regarding the varying responses to chemotherapy of different tumor types. Future trials may give shorter courses of more intense chemotherapy followed by conformal radiotherapy. Conformal techniques allow the delivery of radiation to strictly defined fields and may limit side effects.

In older children with malignant glioma, the current approach is surgical resection of the tumor and combined-modality treatment with irradiation and intensive chemotherapy. In patients with glioblastoma, the use of high-dose chemotherapy and autologous bone marrow or peripheral stem cell reconstitution is being studied. Initial results have been mixed, but the toxicity of such therapy remains a concern. Surgery is not indicated for diffuse brainstem...
gliomas. Traditional treatment of these tumors has been local irradiation. Hyperfractionation to increase the dose from the conventional 54 Gy to 72–78 Gy showed no apparent benefit in a recent Children’s Cancer Group (CCG) study. New approaches are needed for this prognostically poor tumor.

The treatment of low-grade astrocytomas is evolving. Increasing numbers of young children are receiving antitumor chemotherapeutic agents such as carboplatin and vincristine after incomplete resection of these tumors. The role of irradiation after subtotal resection even in older children is being questioned.

**Prognosis**

Despite improvements in surgery and radiation therapy, the outlook for cure remains poor for children with high-grade glial tumors. For children with high-grade gliomas, an early CCG study showed a 45% progression-free survival rate for children who received radiation therapy and chemotherapy. A follow-up CCG study in which all patients had chemotherapy and radiation therapy showed a 5-year progression-free survival rate of 36%. There is a possibility of effective salvage therapy with high-dose chemotherapy for children who relapse. In addition, the extent of resection appeared to correlate positively with prognosis, with a 3-year progression-free survival rate of 17% for patients receiving biopsy only, 29–32% for patients receiving partial or subtotal resections, and 54% for those receiving 90% resections. Biologic factors that may affect survival are being increasingly recognized. The prognosis for diffuse pontine gliomas remains very poor, with no benefit from high-dose chemotherapy plus radiation therapy versus radiation alone.

The 5- and even 10-year survival rate for low-grade astrocytomas of childhood is 60–90%. However, prognosis depends on both site and grade. A child with a pilocytic astrocytoma of the cerebellum has a considerably better prognosis than a child with a fibrillary astrocytoma of the cerebral cortex. Recently, a new entity of low-grade tumor of childhood, the pilomyxoid astrocytoma has been recognized. Pilomyxoid astrocytomas seem to have a worse prognosis than juvenile pilocytic astrocytomas. For recurrent or progressive low-grade astrocytoma of childhood, relatively moderate chemotherapy may improve the likelihood of survival.

Conventional craniospinal irradiation for children with low-stage medulloblastoma results in survival rates of 60–90%. Ten-year survival rates are lower (40–60%). Chemotherapy allows a reduction in the craniospinal radiation dose while preserving survival rates for average-risk patients (86% survival at 5 years on the most recent COG average-risk protocol). However, even reduced-dose craniospinal irradiation has an adverse effect on intellect, especially in children younger than age 7 years. Five-year survival rates for high-risk medulloblastoma have been 25–40%, but a recent trial reported at the American Society of Clinical Oncology (ASCO) conference in 2007 suggests a dramatically improved prognosis for patients receiving intensive chemotherapy and irradiation. Children with supratentorial primitive neuroectodermal tumors also benefit from the addition of chemotherapy to craniospinal irradiation.

Major challenges remain in treating brain tumors in children younger than age 3 years and in treating brainstem gliomas and malignant gliomas. The increasing emphasis is on the quality of life of survivors, not just the survival rate.

---

**LYMPHOMAS & LYMPHOPROLIFERATIVE DISORDERS**

The term *lymphoma* refers to a malignant proliferation of lymphoid cells, usually in association with and arising from lymphoid tissues (ie, lymph nodes, thymus, spleen). In contrast, the term *leukemia* refers to a malignancy arising from the bone marrow, which may include lymphoid cells. Because lymphomas can involve the bone marrow, the distinction between the two can be confusing. The diagnosis of lymphoma is a common one among childhood cancers, accounting for 10–15% of all malignancies. The most common form is Hodgkin disease, which represents nearly half of all cases. The remaining subtypes, referred to collectively as non-Hodgkin lymphoma, are divided into four main groups: lymphoblastic, small noncleaved cell, large B-cell, and anaplastic large cell lymphomas.

In contrast to lymphomas, lymphoproliferative disorders (LPDs) are quite rare in the general population. Most are polyclonal, nonmalignant (though often life-threatening) accumulations of lymphocytes that occur when the immune system fails to control virally transformed lymphocytes. However, a malignant monoclonal proliferation can also arise. The post-transplant LPDs arise in patients who are immunosuppressed to prevent solid organ or bone marrow transplant rejection, particularly liver and heart transplant patients. Spontaneous LPDs occur in immunodeficient individuals and, less commonly, in immunocompetent persons.
1. Hodgkin Disease

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Painless cervical (70–80%) or supraclavicular (25%) adenopathy; mediastinal mass (50%).
- Fatigue, anorexia, weight loss, fever, night sweats, pruritus, cough.

**General Considerations**

Children with Hodgkin disease have a better response to treatment than do adults, with a 75% overall survival rate at more than 20 years following diagnosis. Although adult therapies are applicable, the management of Hodgkin disease in children younger than age 18 years frequently differs. Because excellent disease control can result from several different therapeutic approaches, selection of staging procedures (radiographic, surgical, or other procedures to determine additional locations of disease) and treatment are often based on the potential long-term toxicity associated with the intervention.

Although Hodgkin disease represents 50% of the lymphomas of childhood, only 15% of all cases occur in children aged 16 years or younger. Children younger than age 5 years account for 3% of childhood cases. There is a 4:1 male predominance in the first decade. Notably, in underdeveloped countries the age distribution is quite different, with a male predominance in the first decade. Notably, in underdeveloped countries the age distribution is quite different, with a peak incidence in younger children.

Hodgkin disease is subdivided into four histologic groups, and the distribution in children parallels that of adults: lymphocyte-predominant (10–20%); nodular sclerosing (40–60%) (increases with age); mixed cellularity (20–40%); and lymphocyte-depleted (5–10%). Prognosis is independent of subclassification, with appropriate therapy based on stage (see later discussion of staging).

**Clinical Findings**

**A. Symptoms and Signs**

Children with Hodgkin disease usually present with painless cervical adenopathy. The lymph nodes often feel firmer than inflammatory nodes and have a rubbery texture. They may be discrete or matted together and are not fixed to surrounding tissue. The growth rate is variable, and involved nodes may wax and wane in size over weeks to months.

As Hodgkin disease nearly always arises in lymph nodes and spreads to contiguous nodal groups, a detailed examination of all nodal sites is mandatory. Lymphadenopathy is common in children, so the decision to perform biopsy is often difficult or delayed for a prolonged period. Indications for consideration of early lymph node biopsy include lack of identifiable infection in the region drained by the enlarged node, a node greater than 2 cm in size, supraclavicular adenopathy or abnormal chest radiograph, and lymphadenopathy increasing in size after 2 weeks or failing to resolve within 4–8 weeks.

Constitutional symptoms occur in about one third of children at presentation. Symptoms of fever greater than 38.0°C, weight loss of 10% in the previous 6 months, and drenching night sweats are defined by the Ann Arbor staging criteria as B symptoms. The A designation refers to the absence of these symptoms. B symptoms are of prognostic value, and more aggressive therapy is usually required for cure. Generalized pruritus and pain with alcohol ingestion may also occur.

Half of patients have asymptomatic mediastinal disease (adenopathy or anterior mediastinal mass), although symptoms due to compression of vital structures in the thorax may occur. A chest radiograph should be obtained when lymphoma is being considered. The mediastinum must be evaluated thoroughly before any surgical procedure is undertaken to avoid airway obstruction or cardiovascular collapse during anesthesia and possible death. Splenomegaly or hepatomegaly is generally associated with advanced disease.

**B. Laboratory Findings**

The CBC is usually normal, although anemia, neutrophilia, eosinophilia, and thrombocytosis may be present. The erythrocyte sedimentation rate and other acute-phase reactants are often elevated and can serve as markers of disease activity. Immunologic abnormalities occur, particularly in cell-mediated immunity, and anergy is common in patients with advanced-stage disease at diagnosis. Autoantibody phenomena such as hemolytic anemia and an idiopathic thrombocytopenic purpura–like picture have been reported.

**C. Staging**

Staging of Hodgkin disease determines treatment and prognosis. The most common staging system is the Ann Arbor classification that describes extent of disease by I–IV and symptoms by an A or a B suffix (eg, stage IIIIB). A systematic search for disease includes chest radiography; CT scan of the chest, abdomen, and pelvis; and bilateral bone marrow aspirates and biopsies. Technetium bone scanning may show bony involvement and is usually reserved for patients with bone pain, as bone involvement is rare. Gallium scanning defines gallium-avid tumors and is most useful in evaluating residual mediastinal disease at the completion of treatment. Positron emission tomography is increasingly used in the staging and follow-up of patients with Hodgkin disease, often replacing gallium scanning.

The staging laparotomy in pediatrics is rarely performed because almost all patients are given systemic chemotherapy rather than radiation therapy. This shift in favored therapy is due to the toxicities of high-dose, extended-field radiation in children and the complications of laparotomy, including post-splenectomy sepsis.
D. Pathologic Findings

The diagnosis of Hodgkin disease requires the histologic presence of the Reed-Sternberg cell or its variants in tissue. Reed-Sternberg cells are germinal-center B cells that have undergone malignant transformation. Nearly 20% of these tumors in developed countries are positive for EBV, and there is building evidence to implicate EBV in the development of Hodgkin disease.

Treatment & Prognosis

To achieve long-term disease-free survival while minimizing treatment toxicity, Hodgkin disease is increasingly treated by chemotherapy alone—and less often by radiation therapy.

Several combinations of chemotherapeutic agents are effective, and treatment times are relatively short compared with pediatric oncology protocols for leukemia. A current COG study is addressing whether only 9 weeks of therapy with AV-PC (Adriamycin [doxorubicin], vincristine, prednisone, and cyclophosphamide) is sufficient to induce a complete response in patients with low-risk Hodgkin disease. Two additional drugs, bleomycin and etoposide, are currently added in the treatment of intermediate-risk patients for a total of 4–6 months of therapy for patients with intermediate-risk disease. The removal of involved field irradiation in patients with intermediate-risk Hodgkin disease who respond early to chemotherapy is being investigated. Combined-modality therapy with chemotherapy and irradiation is used in advanced disease.

Current treatment gives children with stage I and stage II Hodgkin disease at least a 90% disease-free likelihood of survival 5 years after diagnosis, which generally equates with cure. Two thirds of all relapses occur within 2 years after diagnosis, and relapse rarely occurs beyond 4 years. In more advanced disease (stages III and IV), 5-year event-free survival rates range from over 60% to 90%. With more patients being long-term survivors of Hodgkin disease, the risk of secondary malignancies, both leukemias and solid tumors, is becoming more apparent and is higher in patients receiving radiation therapy. Therefore, elucidating the optimal treatment strategy that minimizes such risk should be the goal of future studies.

Patients with relapsed Hodgkin disease are often salvageable using chemotherapy and radiation therapy. An increasingly popular alternative is autologous HSCT, which may improve survival rates. Allogeneic HSCT is also used, but carries increased risks of complications and may not offer added survival benefit.
Clinical Findings
A. Symptoms and Signs

Childhood NHLs can arise in any site of lymphoid tissue, including lymph nodes, thymus, liver, and spleen. Common extralymphatic sites include bone, bone marrow, CNS, skin, and testes. Signs and symptoms at presentation are determined by the location of lesions and the degree of dissemination. Because NHL usually progresses very rapidly, the duration of symptoms is quite brief, from days to a few weeks. Nevertheless, children present with a limited number of syndromes, most of which correlate with cell type.

Children with LL often present with symptoms of airway compression (cough, dyspnea, orthopnea) or superior vena cava obstruction (facial edema, chemosis, plethora, venous engorgement), which are a result of mediastinal disease. These symptoms are a true emergency necessitating rapid diagnosis and treatment. Pleural or pericardial effusions may further compromise the patient’s respiratory and cardiovascular status. CNS and bone marrow involvement are not common at diagnosis. When bone marrow contains more than 25% lymphoblasts, patients are diagnosed with ALL.

Most patients with BL and BLL present with abdominal disease. Abdominal pain, distention, a right lower quadrant mass, or intussusception in a child older than age 5 years suggests the diagnosis of BL. Bone marrow involvement is common (~65% of patients). BL is the most rapidly proliferating tumor known and has a high rate of spontaneous cell death as it outgrows its blood supply. Consequently, children presenting with massive abdominal disease frequently have tumor lysis syndrome (hyperuricemia, hyperphosphatemia, and hyperkalemia). These abnormalities can be aggravated by tumor infiltration of the kidney or urinary obstruction by tumor. Although similar histologically, numerous differences exist between cases of BL occurring in endemic areas of equatorial Africa and the sporadic cases of North America (Table 29–6).

CNS, central nervous system; EBV, Epstein-Barr virus.
Large cell lymphomas are similar clinically to the small noncleaved cell lymphomas, although unusual sites of involvement are quite common, particularly with ALCL. Skin lesions, focal neurologic deficits, and pleural or peritoneal effusions without an obvious associated mass are frequently seen.

B. Diagnostic Evaluation

Diagnosis is made by biopsy of involved tissue with histology, immunophenotyping, and cytogenetic studies. If mediastinal disease is present, general anesthesia must be avoided if the airway or vena cava is compromised by tumor. In these cases samples of pleural or ascitic fluid, bone marrow, or peripheral nodes obtained under local anesthesia may confirm the diagnosis. Major abdominal surgery and intestinal resection should be avoided in patients with an abdominal mass that is likely to be BL, as the tumor will regress rapidly with the initiation of chemotherapy. The rapid growth of these tumors and the associated life-threatening complications demand that further studies be done expeditiously so that specific therapy is not delayed.

After a thorough physical examination, a CBC, liver function tests, and a biochemical profile (electrolytes, calcium, phosphorus, uric acid, renal function) should be obtained. An elevated LDH reflects tumor burden and can serve as a marker of disease activity. Imaging studies should include a chest radiograph and chest CT scan, an abdominal ultrasound or CT scan, and possibly a gallium or positron emission tomography scan. Bone marrow and CSF examinations are also essential.

▶ Treatment

A. Supportive Care

The management of life-threatening problems at presentation is critical. The most common complications are severe mediastinal syndrome and acute tumor lysis syndrome. Patients with airway compromise require prompt initiation of specific therapy. Because of the risk of general anesthesia in these patients, it is occasionally necessary to initiate corticosteroids or low-dose emergency radiation therapy until the mass is small enough for a biopsy to be undertaken safely. Response to steroids and radiation therapy is usually prompt (12–24 hours).

Tumor lysis syndrome should be anticipated in all patients who have NHL with a large tumor burden. Maintaining a brisk urine output (> 5 mL/kg/h) with intravenous fluids and diuretics is the key to management. Allopurinol will reduce serum uric acid, and alkalization of urine will increase its solubility. Rasburicase is an effective intravenous alternative to allopurinol. Because phosphate precipitates in alkaline urine, alkali administration should be discontinued if hyperphosphatemia occurs. Renal dialysis is occasionally necessary to control metabolic abnormalities. Every attempt should be made to correct or minimize metabolic abnormalities before initiating chemotherapy; however, this period of stabilization should not exceed 24–48 hours.

B. Specific Therapy

Systemic chemotherapy is the mainstay of therapy for NHLs. Nearly all patients with NHL require intensive intrathecal chemotherapy for CNS prophylaxis. Surgical resection is not indicated unless the entire tumor can be resected safely, which is rare. Partial resection or debulking surgery has no role. Radiation therapy does not improve outcome, so its use is confined to exceptional circumstances.

Therapy for LL is generally based on treatment protocols designed for ALL and involves dose-intensive, multiagent chemotherapy. The duration of therapy is 2 years. Treatment of BL and BLL using alkylating agents and intermediate- to high-dose methotrexate administered intensively but for a relatively short time produce the highest cure rates. LBCL is treated similarly, whereas ALCL has been treated with both BL and LL protocols.

Monoclonal antibodies such as rituximab (anti-CD20) allow for more targeted therapy of lymphomas and have been successful in improving outcomes in adults. Studies employing this type of therapy in children are underway in those with newly diagnosed as well as relapsed or refractory B-cell NHL.

▶ Prognosis

A major predictor of outcome in NHL is the extent of disease at diagnosis. Ninety percent of patients with localized disease can expect long-term, disease-free survival. Patients with extensive disease on both sides of the diaphragm, CNS involvement, or bone marrow involvement in addition to a primary site have a 70–80% failure-free survival rate. Relapses occur early in NHL; patients with LL rarely have recurrences after 30 months from diagnosis, whereas patients with BL and BLL very rarely have recurrences beyond 1 year. Patients who experience relapse may have a chance for cure by autologous or allogeneic HSCT.

3. Lymphoproliferative Disorders

LPDs can be thought of as a part of a continuum with lymphomas. Whereas LPDs represent inappropriate, often polyclonal proliferations of nonmalignant lymphocytes,
lymphomas represent the development of malignant clones, sometimes arising from recognized LPDs.

**A. Post-Transplantation Lymphoproliferative Disorders**

Post-transplantation lymphoproliferative disorders (PTLDs) arise in patients who have received substantial immunosuppressive medications for solid organ or bone marrow transplantation. In these patients, reactivation of latent EBV infection in B cells drives a polyclonal proliferation of these cells that is fatal if not halted. Occasionally a true lymphoma develops, often bearing a chromosomal translocation.

LPDs are an increasingly common and significant complication of transplantation. The incidence of PTLD ranges from approximately 2% to 15% of transplant recipients, depending on the organ transplanted and the immunosuppressive regimen.

Treatment of these disorders is a challenge for transplant physicians and oncologists. The initial treatment is reduction in immunosuppression, which allows the patient’s own immune cells to destroy the virally transformed lymphocytes. However, this is only effective in approximately half of the patients. For those patients who do not respond to reduced immune suppression, chemotherapy of various regimens may succeed. The use of anti-B-cell antibodies, such as rituximab (anti-CD20), for the treatment of PTLDs has been promising in clinical trials.

**B. Spontaneous Lymphoproliferative Disease**

Immunodeficiencies in which LPDs occur include Bloom syndrome, Chédiak–Higashi syndrome, ataxia-telangiectasia, Wiskott-Aldrich syndrome, X-linked lymphoproliferative syndrome, congenital T-cell immunodeficiencies, and HIV infection. Treatment depends on the circumstances, but unlike PTLD, few therapeutic options are often available. Castleman disease is an LPD occurring in pediatric patients without any apparent immunodeficiency. The autoimmune lymphoproliferative syndrome (ALPS) is characterized by widespread lymphadenopathy with hepatosplenomegaly, and autoimmune phenomena. ALPS results from mutations in the Fas ligand pathway that is critical in regulation of apoptosis.

**NEUROBLASTOMA**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Bone pain, abdominal pain, anorexia, weight loss, fatigue, fever, irritability.
- Abdominal mass (65%), adenopathy, proptosis, periorbital ecchymosis, skull masses, subcutaneous nodules, hepatomegaly, spinal cord compression.

**General Considerations**

Neuroblastoma arises from neural crest tissue of the sympathetic ganglia or adrenal medulla. It is composed of small, fairly uniform cells with little cytoplasm and hyperchromatic nuclei that may form rosette patterns. Pathologic diagnosis is not always easy, and neuroblastoma must be differentiated from the other “small, round, blue cell” malignancies of childhood (Ewing sarcoma, rhabdomyosarcoma, peripheral neuroectodermal tumor, and lymphoma).

Neuroblastoma accounts for 7–10% of pediatric malignancies and is the most common solid neoplasm outside the CNS. Fifty percent of neuroblastomas are diagnosed before age 2 years and 90% before age 5 years.

Neuroblastoma is a biologically diverse disease with varied clinical behavior ranging from spontaneous regression to progression through very aggressive therapy. Unfortunately, despite significant advances in our understanding of this tumor at the cellular and molecular level, the overall survival rate in advanced disease has changed little in 20 years, with 3-year event-free survival being less than 15%.

**Clinical Findings**

**A. Symptoms and Signs**

Clinical manifestations vary with the primary site of malignant disease and the neuroendocrine function of the tumor. Many children present with constitutional symptoms such as fever, weight loss, and irritability. Bone pain suggests metastatic disease, which is present in 60% of children older than 1 year of age at diagnosis. Physical examination may reveal a firm, fixed, irregularly shaped mass that extends beyond the midline. The margins are often poorly defined. Although most children have an abdominal primary tumor (40% adrenal gland, 25% paraspinal ganglion), neuroblastoma can arise wherever there is sympathetic tissue. In the posterior mediastinum, the tumor is usually asymptomatic and discovered on a chest radiograph obtained for other reasons. Patients with cervical neuroblastoma present with a neck mass, which is often misdiagnosed as infection. Horner syndrome (unilateral ptosis, myosis, and anhydrosis) or heterochromia iridis (differently colored irises) may accompany cervical neuroblastoma. Paraspinous tumors can
extend through the spinal foramina, causing cord compression. Patients may present with paresis, paralysis, and bowel or bladder dysfunction.

The most common sites of metastases are bone, bone marrow, lymph nodes (regional as well as disseminated), liver, and subcutaneous tissue. Neuroblastoma has a predilection for metastasis to the skull, in particular the sphenoid bone and retrobulbar tissue. This causes periorbital ecchymosis and proptosis. Liver metastasis, particularly in the newborn, can be massive. Subcutaneous nodules are bluish in color and associated with an erythematous flush followed by blanching when compressed, probably secondary to catecholamine release.

Neuroblastoma may also be associated with unusual paraneoplastic manifestations. Perhaps the most striking example is opsoclonus-myoclonus, also called dancing eyes/dancing feet syndrome. This phenomenon is characterized by the acute onset of rapid and chaotic eye movements, myoclonic jerking of the limbs and trunk, ataxia, and behavioral disturbances. This process, which often persists after therapy is complete, is thought to be secondary to cross-reacting antineural antibodies. Intractable, chronic watery diarrhea is associated with tumor secretion of vasoactive intestinal peptides. Both of these paraneoplastic syndromes are associated with favorable outcomes.

B. Laboratory Findings

Anemia is present in 60% of children with neuroblastoma and can be due to chronic disease or marrow infiltration. Occasionally, thrombocytopenia is present, but thrombocytosis is a more common finding, even with metastatic disease in the marrow. Urinary catecholamines (vanillylmandelic acid and homovanillic acid) are elevated in at least 90% of patients at diagnosis and should be measured prior to surgery.

C. Imaging

Plain radiographs of the primary tumor may show stippled calcifications. Metastases to bone appear irregular and lytic. Periosteal reaction and pathologic fractures may also be seen. CT scanning provides more information, including the extent of the primary tumor, its effects on surrounding structures, and the presence of liver and lymph node metastases. Classically, in tumors originating from the adrenal gland, the kidney is displaced inferolaterally, which helps to differentiate neuroblastoma from Wilms tumor. MRI is useful in determining the presence of spinal cord involvement in tumors that appear to invade neural foramina.

Technetium bone scanning is obtained for the evaluation of bone metastases, because the tumor usually takes up technetium Metaiodobenzyl-guanidine (MIBG) scanning is also performed to detect metastatic disease.

D. Staging

Staging of neuroblastoma is performed according to the International Neuroblastoma Staging System (INSS) (Table 29–7). A biopsy of the tumor is performed to determine the biologic characteristics of the tumor. In addition, bilateral bone marrow aspirates and biopsies must be performed to evaluate marrow involvement.

Tumors are classified as favorable or unfavorable based on histologic characteristics. Amplification of the MYCN protooncogene is a reliable marker of aggressive clinical behavior with rapid disease progression. Tumor cell DNA content is also predictive of outcome. Hyperdiploidy is a favorable finding, whereas diploid DNA content is associated with a worse outcome.

</tbody>
</table>

Treatment & Prognosis

Patients are treated based on a risk stratification system adopted by the COG based on INSS stage, age, MYCN status, histology, and DNA index. The mainstay of therapy is surgical resection coupled with chemotherapy. The usually massive size of the tumor often makes primary resection impossible. Under these circumstances, only a biopsy is performed. Following chemotherapy, a second surgical procedure may allow for resection of the primary tumor. Radiation therapy is sometimes also necessary. Effective chemotherapeutic agents in the treatment of neuroblastoma include cyclophosphamide, doxorubicin, etoposide, cisplatin, vincristine, and topotecan. About 80% of patients achieve
complete or partial remission, although in advanced disease, remission is seldom durable.

For low-risk disease (stage 1 and 2, with good biologic features), surgical resection alone may be sufficient to affect a cure. Infants younger than 1 year with stage 4S disease may need little if any therapy, although chemotherapy may be initiated because of bulky disease causing mechanical complications. In intermediate-risk neuroblastoma (subsets of patients with stage 3 and 4 disease) the primary treatment approach is surgical combined with chemotherapy. High-risk patients (the majority with stage 3 and 4 disease) require multimodal therapy, including surgery, irradiation, chemotherapy, and autologous HSCT. The administration of cis-retinoic acid, a differentiating agent, can prolong disease-free survival in advanced-stage neuroblastoma when administered in the setting of minimal residual disease (MRD) after HSCT.

Cooperative clinical trials are underway in high-risk patients using ch14.18 (a monoclonal antibody specific for the predominant antigen on neuroblastoma cells) and cytokines to eradicate MRD. A phase II study is underway using fenretinide, a synthetic retinoid, and radiolabeled MIBG to determine whether pulmonary metastases are present.

For children with stage 1, 2, or 4S disease, the 5-year survival rate is 70–90%. Infants younger than 460 days old have a greater than 80% likelihood of long-term survival. Children older than age 1 year with stage 3 disease have an intermediate prognosis (approximately 40–70%). Older patients with stage 4 disease have a poor prognosis (5–50% survival 5 years from diagnosis), although patients 12–18 months old with hyperdiploidy and nonamplified MYCN have an excellent prognosis.

For children with stage 1, 2, or 4S disease, the 5-year survival rate is 70–90%. Infants younger than 460 days old have a greater than 80% likelihood of long-term survival. Children older than age 1 year with stage 3 disease have an intermediate prognosis (approximately 40–70%). Older patients with stage 4 disease have a poor prognosis (5–50% survival 5 years from diagnosis), although patients 12–18 months old with hyperdiploidy and nonamplified MYCN have an excellent prognosis.

**WILMS TUMOR (NEPHROBLASTOMA)**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Asymptomatic abdominal mass or swelling (83%).
- Fever (23%), hematuria (21%).
- Hypertension (25%), genitourinary malformations (6%), aniridia, hemihypertrophy.

**General Considerations**

Approximately 460 new cases of Wilms tumor occur annually in the United States, representing 3–6% of cancers in children younger than age 15 years. After neuroblastoma, this is the second most common abdominal tumor in children. The majority of Wilms tumors are of sporadic occurrence. However, in a few children, Wilms tumor occurs in the setting of associated malformations or syndromes, including aniridia, hemihypertrophy, genitourinary malformations (eg, cryptorchidism, hypospadias, gonadal dysgenesis, pseudohermaphroditism, and horseshoe kidney), Beckwith-Wiedemann syndrome, Denys-Drash syndrome, and WAGR syndrome (Wilms tumor, aniridia, ambiguous genitalia, mental retardation).

The median age at diagnosis is related both to gender and laterality, with bilateral tumors presenting at a younger age than unilateral tumors, and males being diagnosed earlier than females. Wilms tumor occurs most commonly between ages 2 and 5 years; it is unusual after age 6 years. The mean age at diagnosis is 4 years.

**Clinical Findings**

**A. Symptoms and Signs**

Most children with Wilms tumor present with increasing size of the abdomen or an asymptomatic abdominal mass incidentally discovered by a parent. The mass is usually smooth and firm, well demarcated, and rarely crosses the midline, though it can extend inferiorly into the pelvis. About 25% of patients are hypertensive at presentation. Gross hematuria is an uncommon presentation, although microscopic hematuria occurs in approximately 25% of patients.

**B. Laboratory Findings**

The CBC is usually normal, but some patients have anemia secondary to hemorrhage into the tumor. Blood urea nitrogen and serum creatinine are usually normal. Urinalysis may show some blood or leukocytes.

**C. Imaging and Staging**

Ultrasoundography or CT of the abdomen should establish the presence of an intrarenal mass. It is also essential to evaluate the contralateral kidney for presence and function as well as synchronous Wilms tumor. The inferior vena cava needs to be evaluated by ultrasonography for the presence and extent of tumor propagation. The liver should be imaged for the presence of metastatic disease. A plain chest radiograph (four views) or chest CT scans (or both) should be obtained to determine whether pulmonary metastases are present.
Approximately 10% of patients will have metastatic disease at diagnosis. Of these, 80% will have pulmonary disease and 15% liver metastases. Bone and brain metastases are extremely uncommon and usually associated with different, more aggressive renal tumors, such as clear cell sarcoma or rhabdoid tumor; hence, bone scans and brain imaging are not routinely performed. The clinical stage is ultimately decided at surgery and confirmed by the pathologist.

### Treatment & Prognosis

In the United States, treatment of Wilms tumor begins with surgical exploration of the abdomen via an anterior surgical approach to allow for inspection and palpation of the contralateral kidney. The liver and lymph nodes are inspected and suspicious areas biopsied or excised. En bloc resection of tumor is performed. Every attempt is made to avoid tumor spillage at surgery as this may change staging and treatment. Because therapy is tailored to tumor stage, it is imperative that a surgeon familiar with the staging requirements perform the operation.

In addition to the staging, the histologic type has implications for therapy and prognosis. Favorable histology (FH; see later discussion) refers to the classic triphasic Wilms tumor and its variants. Unfavorable histology (UH) refers to the presence of diffuse anaplasia (extreme nuclear atypia) and is present in 5% of Wilms tumors. Only a few small foci of anaplasia in a Wilms tumor give a worse prognosis to patients with stage II, III, or IV tumors. Loss of heterozygosity of chromosomes 1p and 16q are adverse prognostic factors in those with favorable histology. Following excision and pathologic examination, the patient is assigned a stage that defines further therapy.

Improvement in the treatment of Wilms tumor has resulted in an overall cure rate of approximately 90%. The National Wilms Tumor Study Group’s fourth study (NWTS-4) demonstrated that survival rates were improved by intensifying therapy during the initial treatment phase while shortening overall treatment duration (24 weeks vs 60 weeks of treatment).

Table 29–8 provides an overview of the current treatment recommendations in NWTS-5. Patients with stage III or IV Wilms tumor require radiation therapy to the tumor bed and to sites of metastatic disease. Chemotherapy is optimally begun within 5 days after surgery, whereas radiation therapy should be started within 10 days. Stage V (bilateral Wilms tumor) disease dictates a different approach, consisting of possible bilateral renal biopsies followed by chemotherapy and second-look renal-sparing surgery. Radiation therapy may also be necessary.

Using these approaches, 4-year overall survival rates through NWTS-4 are as follows: stage I FH, 96%; stage II–IV FH, 82–92%; stage I–III UH (diffuse anaplasia), 56–70%; stage IV UH, 17%. Patients with recurrent Wilms tumor have a salvage rate of approximately 50% with surgery, radiation therapy, and chemotherapy ( singly or in combination). HSCT is also being explored as a way to improve the chances of survival after relapse.

### Future Considerations

Although progress in the treatment of Wilms tumor has been extraordinary, important questions remain to be answered. Questions have been raised regarding the role of prenephrectomy chemotherapy in the treatment of Wilms tumor. Presurgical chemotherapy seems to decrease tumor rupture at resection but may unfavorably affect outcome by changing staging. Future studies will be directed at minimizing acute and long-term toxicities for those with low-risk disease and improving outcomes for those with high-risk and recurrent disease.

FH, favorable histology; UH, unfavorable histology.
The cardinal signs of bone tumor are pain at the site of involvement, often following slight trauma, mass formation, and fracture through an area of cortical bone destruction.

1. Osteosarcoma

General Considerations

Although osteosarcoma is the sixth most common malignancy in childhood, it ranks third among adolescents and young adults. This peak occurrence during the adolescent growth spurt suggests a causal relationship between rapid bone growth and malignant transformation. Further evidence for this relationship is found in epidemiologic data showing patients with osteosarcoma to be taller than their peers, osteosarcoma occurring most frequently at sites where the greatest increase in length and size of bone occurs, and osteosarcoma occurring at an earlier age in girls than boys, corresponding to their earlier growth spurt. The metaphyses of long tubular bones are primarily affected. The distal femur accounts for more than 40% of cases, with the proximal tibia, proximal humerus, and mid and proximal femur following in frequency.

Clinical Findings

A. Symptoms and Signs

Pain over the involved area is the usual presenting symptom with or without an associated soft tissue mass. Patients generally have symptoms for several months prior to diagnosis. Systemic symptoms (fever, weight loss) are rare. Laboratory evaluation may reveal elevated serum alkaline phosphatase or LDH levels.

B. Imaging and Staging

Radiographic findings show permeative destruction of the normal bony trabecular pattern with indistinct margins. In addition, periosteal new bone formation and lifting of the bony cortex may create a Codman triangle. A soft tissue mass plus calcifications in a radial or sunburst pattern are frequently noted. MRI is more sensitive in defining the extent of the primary tumor and in many centers has replaced CT scanning. The most common sites of metastases are the lung (≤ 20% of newly diagnosed cases) and the bone (10%). CT scan of the chest and bone scan are essential for detecting metastatic disease. Bone marrow aspirates and biopsies are not indicated.

Despite the rather characteristic radiographic appearance, a tissue sample is needed to confirm the diagnosis. Placement of the incision for biopsy is of critical importance. A misplaced incision could preclude a limb salvage procedure and necessitate amputation. The surgeon who will carry out the definitive surgical procedure should perform the biopsy. A staging system for osteosarcoma based on local tumor extent and presence or absence of distant metastasis has been proposed, but it has not been validated.

Treatment & Prognosis

Historical studies showed that over 50% of patients receiving surgery alone developed pulmonary metastases within 6 months after surgery. This suggests the presence of micrometastatic disease at diagnosis. Adjuvant chemotherapy trials showed improved disease-free survival rates of 55–85% in patients followed for 3–10 years.

Osteosarcomas are highly radioresistant lesions; for this reason, radiation therapy has no role in its primary management. Chemotherapy is often administered prior to definitive surgery (neoadjuvant chemotherapy). This permits an early attack on micrometastatic disease and may also shrink the tumor, facilitating a limb salvage procedure. Preoperative chemotherapy also makes detailed histologic evaluation of tumor response to the chemotherapy agents possible. If the histologic response is poor (> 10% viable tumor tissue), postoperative chemotherapy can be changed accordingly. Chemotherapy may be administered intra-arterially or intra-venously, although the benefits of intra-arterial chemotherapy are disputed. Agents having efficacy in the treatment of osteosarcoma include doxorubicin, cisplatin, high-dose methotrexate, and ifosfamide.

Definitive cure requires en bloc surgical resection of the tumor with a margin of uninvolved tissue. Amputation and limb salvage are equally effective in achieving local control of osteosarcoma. Contraindications to limb-sparing surgery include major involvement of the neurovascular bundle by tumor; immature skeletal age, particularly for lower extremity tumors; infection in the region of the tumor; inappropriate biopsy site; and extensive muscle involvement that would result in a poor functional outcome.

Postoperative chemotherapy is generally continued until the patient has received 1 year of treatment. Relapses are unusual beyond 3 years, but late relapses do occur. Histologic response to neoadjuvant chemotherapy is an excellent predictor of outcome. Patients with localized disease having 90% tumor necrosis have a 70–85% long-term, disease-free survival rate. Other favorable prognostic factors include distal skeletal lesions, longer duration of symptoms, age older than 20 years, female gender, and near-diploid tumor DNA index. Patients with metastatic disease at diagnosis or multifocal bone lesions do not fair well, despite advances in chemotherapy and surgical techniques.

2. Ewing Sarcoma

General Considerations

Ewing sarcoma accounts for only 10% of primary malignant bone tumors; fewer than 200 new cases occur each year in the United States. It is a disease primarily of white males, almost never affects blacks, and occurs mostly in the second decade of life. Ewing sarcoma is considered a “small, round, blue cell” malignancy. The differential diagnosis includes rhabdomyosarcoma, lymphoma, and neuroblastoma. Although most commonly a tumor of bone, it may also occur in soft
tissue (extraosseous Ewing sarcoma or peripheral neuroectodermal tumor [PNET]).

Clinical Findings

A. Symptoms and Signs

Pain at the site of the primary tumor is the most common presenting sign, with or without swelling and erythema. No specific laboratory findings are characteristic of Ewing sarcoma, but an elevated LDH may be present and is of prognostic significance.

B. Imaging and Staging

The radiographic appearance of Ewing sarcoma overlaps with osteosarcoma, although Ewing sarcoma usually involves the diaphyses of long bones. The central axial skeleton gives rise to 40% of Ewing tumors. Evaluation of a patient diagnosed as having Ewing sarcoma should include CT scan or MRI (or both) of the primary lesion to define the extent of local disease as precisely as possible. This is imperative for planning future surgical procedures or radiation therapy. Metastatic disease is present in 25% of patients at diagnosis. The lung (38%), bone (particularly the spine) (31%), and the bone marrow (11%) are the most common sites for metastasis. CT scan of the chest, bone scanning, and bilateral bone marrow aspirates and biopsies are all essential to the staging workup.

A biopsy is essential in establishing the diagnosis. Histologically, Ewing sarcoma consists of sheets of undifferentiated cells with hyperchromatic nuclei, well-defined cell borders, and scanty cytoplasm. Necrosis is common. Electron microscopy, immunocytochemistry, and cytogenetics may be necessary to confirm the diagnosis. A generous tissue biopsy specimen is often necessary for diagnosis but should not delay starting chemotherapy.

A consistent cytogenetic abnormality, t(11;22), has been identified in Ewing sarcoma and PNET and is present in 85–90% of tumors. These tumors also express the protooncogene c-myc, which may be helpful in differentiating Ewing sarcoma from neuroblastoma, in which c-myc is not expressed.

Treatment & Prognosis

Therapy usually commences with the administration of chemotherapy after biopsy and is followed by local control measures. Depending on many factors, including the primary site of the tumor and the response to chemotherapy, local control could be achieved by surgery, radiation therapy, or a combination of these methods. Following local control, chemotherapy continues for approximately 1 year. Effective treatment for Ewing sarcoma uses combinations of daunomycin, vincristine, doxorubicin, cyclophosphamide, etoposide, and ifosfamide. Patients with small localized primary tumors have a 50–70% long-term, disease-free survival rate. For patients with metastatic disease and large pelvic primary tumors, survival is poor. Autologous HSCT is being investigated for the treatment of these high-risk patients.

Rhabdomyosarcoma

Rhabdomyosarcoma is the most common soft tissue sarcoma occurring in childhood and accounts for 10% of solid tumors in childhood. The peak incidence is at ages 2–5 years; 70% of children are diagnosed before age 10 years. A second smaller peak is seen in adolescents with extremity tumors. Males are affected more commonly than females.

Rhabdomyosarcoma can occur anywhere in the body. When rhabdomyosarcoma imitates striated muscle and cross-striations are seen by light microscopy, the diagnosis is straightforward. Immunohistochemistry, electron microscopy, or chromosomal analysis is sometimes necessary to make the diagnosis. Rhabdomyosarcoma is further classified into subtypes based on pathologic features: embryonal (60–80%), of which botryoid is a variant; alveolar (about 15–20%); undifferentiated sarcoma (8%); pleomorphic, which is seen in adults (1%); and other (11%). These subtypes occur in characteristic locations and have different metastatic potentials and outcomes.

Although the pathogenesis of rhabdomyosarcoma is unknown, in rare cases a genetic predisposition has been determined. Li-Fraumeni syndrome is an inherited mutation of the p53 tumor suppressor gene that results in a high risk
of bone and soft tissue sarcomas in childhood plus breast cancer and other malignant neoplasms before age 45 years. Two characteristic chromosomal translocations \([t(2;13)\) and \([t(1;13)\)]\) have been described in alveolar rhabdomyosarcoma. The \([t(1;13)\)]\) translocation appears to be a favorable prognostic feature in patients with metastatic alveolar rhabdomyosarcoma, whereas \([t(2;13)\)]\) is associated with poor outcomes.

**Clinical Findings**

**A. Symptoms and Signs**

The presenting symptoms and signs of rhabdomyosarcoma result from disturbances of normal body function due to tumor growth (Table 29–9). For example, patients with orbital rhabdomyosarcoma present with proptosis, whereas patients with rhabdomyosarcoma of the bladder can present with hematuria, urinary obstruction, or a pelvic mass.

**B. Imaging**

A plain radiograph and a CT or MRI scan should be obtained to determine the extent of the primary tumor and to assess regional lymph nodes. A lung CT scan is obtained to rule out pulmonary metastasis, the most common site of metastatic disease at diagnosis. A skeletal survey and a bone scan are obtained to determine whether bony metastases are present. Bilateral bone marrow biopsies and aspirates are obtained to rule out bone marrow infiltration. Additional studies may be warranted in certain sites. For example, in parameningeal primary tumors, a lumbar puncture is performed to evaluate CSF for tumor cells.

**Treatment**

Optimal management and treatment of rhabdomyosarcoma is complex and requires combined modality therapy. When feasible, the tumor should be excised, but this is not always possible because of the site of origin and size of tumor. When only partial tumor resection is feasible, the operative procedure is usually limited to biopsy and sampling of lymph nodes. Debulking of unresectable tumor may improve outcomes. Chemotherapy can often convert an inoperable tumor to a resectable one. A second-look procedure to remove residual disease and confirm the clinical response to chemotherapy and radiation therapy is generally performed at about week 20 of therapy.

Radiation therapy is an effective method of local tumor control for both microscopic and gross residual disease. It is generally administered to all patients, the only exception being those with a localized tumor that has been completely resected. All patients with rhabdomyosarcoma receive chemotherapy, even when the tumor is fully resected at diagnosis. The exact regimen and duration of chemotherapy are determined by primary site, group, and tumor node metastasis classification. Vincristine, dactinomycin, and cyclophosphamide have shown the greatest efficacy in the treatment of rhabdomyosarcoma.

**Prognosis**

The age of the patient, the extent of tumor at diagnosis, the primary site, the pathologic subtype, and the response to treatment all influence the long-term, disease-free survival rate from the time of diagnosis. Children with localized disease at diagnosis have a 70–75% 3-year disease-free survival rate, whereas children with metastatic disease at presentation have a worse outcome (39% 3-year disease-free survival).

Newer treatment strategies for high-risk patients include different drug combinations and dosing schedules with hematopoietic growth factor support, hyperfractionated radiation therapy, and autologous HSCT.

</table>
Children with retinoblastoma generally come to medical attention while the tumor is still confined to the globe. Although present at birth, retinoblastoma is not usually detected until it has grown to a considerable size. Leukocoria (white pupillary reflex) is the most common sign (found in 60% of patients). Parents may note an unusual appearance of the eye or asymmetry of the eyes in a photograph. The differential diagnosis of leukocoria includes *Toxocara canis* granuloma, astrocytic hamartoma, retinopathy of prematurity, Coats disease, and persistent hyperplastic primary vitreous. Strabismus (in 20% of patients) is seen when the tumor involves the macula and central vision is lost. Rarely (in 7% of patients), a painful red eye with glaucoma, a hyphema, or proptosis is the initial manifestation. A single focus or multiple foci of tumor may be seen in one or both eyes at diagnosis. Bilateral involvement occurs in 20–30% of children.

## B. Diagnostic Evaluation

Suspected retinoblastoma requires a detailed ophthalmologic examination under general anesthesia. An ophthalmologist makes the diagnosis of retinoblastoma by the appearance of the tumor within the eye without pathologic confirmation. A white to creamy pink mass protruding into the vitreous matter suggests the diagnosis; intraocular calcifications and vitreous seeding are virtually pathognomonic of retinoblastoma. A CT scan of the orbits detects intraocular calcification, evaluates the optic nerve for tumor infiltration, and detects extraocular extension of tumor. A single focus or multiple foci of tumor may be seen in one or both eyes at diagnosis. Metastatic disease of the marrow and meninges can be ruled out with bilateral bone marrow aspirates and biopsies plus CSF cytology.

## Treatment

Each eye is treated according to the potential for useful vision, and every attempt is made to preserve vision. The choice of therapy depends on the size, location, and number of intraocular lesions. Absolute indications for enucleation include no vision, neovascular glaucoma, inability to examine the treated eye, and inability to control tumor growth with conservative treatment. External beam irradiation has been the mainstay of therapy. A total dose of 35–45 Gy is administered. However, many centers are investigating the role of systemic chemotherapy for the treatment of retinoblastoma confined to the globe and the elimination of external beam radiotherapy is now accepted. Cryotherapy, photocoagulation, and radioactive plaques can be used for local tumor control. Patients with metastatic disease receive chemotherapy.

Children with retinoblastoma confined to the retina (whether unilateral or bilateral) have an excellent prognosis, with 5-year survival rates greater than 90%. Mortality is correlated directly with extent of optic nerve involvement, orbital extension of tumor, and massive choroid invasion. Patients who have disease in the optic nerve beyond the
lamina cribrosa have a 5-year survival rate of only 40%. Patients with meningeal or metastatic spread rarely survive, although intensive chemotherapy and autologous HSCT have produced long-term survivors.

Patients with the germline mutation (heritable form) have a significant risk of developing second primary tumors. Osteosarcomas account for 40% of such tumors. Second malignant neoplasms occur in both patients who have and those who have not received radiation therapy. The 30-year cumulative incidence for a second neoplasm is 35% in patients who received radiation therapy and 6% in those who did not receive radiation therapy. The risk continues to increase over time. Although radiation contributes to the risk, it is the presence of the retinoblastoma gene itself that is responsible for the development of nonocular tumors in these patients.

HEPATIC TUMORS (SEE ALSO CHAPTER 21)

Two thirds of liver masses found in childhood are malignant. Ninety percent of hepatic malignancies are either hepatoblastoma or hepatocellular carcinoma. Hepatoblastoma accounts for the vast majority of liver tumors in children younger than age 5 years, hepatocellular carcinoma for the majority in children aged 15–19 years. The features of these hepatic malignancies are compared in Table 29–10. Of the benign tumors, 60% are hamartomas or vascular tumors such as hemangiomas. There is mounting evidence for a strong association between prematurity and the risk of hepatoblastoma.

Children with hepatic tumors usually come to medical attention because of an enlarging abdomen. Approximately 10% of hepatoblastomas are first discovered on routine examination. Anorexia, weight loss, vomiting, and abdominal pain are associated more commonly with hepatocellular carcinoma. Serum α-fetoprotein is often elevated and is an excellent marker for response to treatment.

Imaging studies should include abdominal ultrasound, CT scan, or MRI. Malignant tumors have a diffuse hyper-echoic pattern on ultrasonography, whereas benign tumors are usually poorly echoic. Vascular lesions contain areas with varying degrees of echogenicity. Ultrasound is also useful for imaging the hepatic veins, portal veins, and inferior vena cava. CT scanning and, in particular, MRI are important for defining the extent of tumor within the liver. CT scanning of the chest and bone scan should be obtained to evaluate for metastatic spread. Because bone marrow involvement is extremely rare, bone marrow aspirations and biopsies are not indicated.

The prognosis for children with hepatic malignancies depends on the tumor type and the resectability of the

AFP, α-fetoprotein.
tumor. Complete resectability is essential for survival. Chemotherapy can decrease the size of most hepatoblastomas. Following biopsy of the lesion, neoadjuvant chemotherapy is administered prior to attempting complete surgical resection. Chemotherapy can often convert an inoperable tumor to a completely resectable one and can also eradicate metastatic disease. Approximately 50–60% of hepatoblastomas are fully resectable, whereas only one third of hepatocellular carcinomas can be completely removed. Even with complete resection, only one third of patients with hepatocellular carcinoma are long-term survivors. A recent CCG/Pediatric Oncology Group trial has shown cisplatin, fluorouracil, and vincristine to be as effective as but less toxic than cisplatin and doxorubicin in treating hepatoblastoma. Other drug combinations that have demonstrated benefit include carboplatin plus etoposide and doxorubicin plus ifosfamide. Radiation as well as liver transplantation is being investigated for patients whose tumors cannot be completely resected following chemotherapy.

**LANGERHANS CELL HISTIOCYTOSIS**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Seborrheic skin rashes.
- Diaper rash.
- Draining ears.
- Bone pain.

**General Considerations**

Langerhans cell histiocytosis (LCH; formerly called histiocytosis X) is a rare and poorly understood spectrum of disorders. It can occur as an isolated lesion or as widespread systemic disease involving virtually any body site. Eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease are all syndromes encompassed by this disorder. LCH is not a true malignancy, but instead is a clonal, reactive proliferation of normal histiocytes, perhaps resulting from an immunoregulatory defect.

The distinctive pathologic feature is proliferation of histiocytic cells beyond what would be seen in a normal inflammatory process. Langerhans histiocytes have typical features: on light microscopy, the nuclei are deeply indented (coffee bean–shaped) and elongated, and the cytoplasm is pale, distinct, and abundant. Additional diagnostic characteristics include Birbeck granules on electron microscopy, expression of CD1 on the cell surface, and positive immunostaining for S-100 protein.

**Clinical Findings**

Because LCH encompasses a broad spectrum of diseases, its presentation can be variable, from a single asymptomatic lesion to widely disseminated disease.

Patients with localized disease present primarily with lesions limited to bone. Occasionally found incidentally on radiographs obtained for other reasons, these lesions are well-demarcated and frequently found in the skull, clavicles, ribs, and vertebrae. These lesions can be painful. Patients can also present with localized disease of the skin, often as a diaper rash that does not resolve.

Bony lesions, fever, weight loss, otitis media, exophthalmos, and diabetes insipidus occur in a small number of children with the disease. Children with this multifocal disease, formerly called Hand-Schüller-Christian disease, commonly present with generalized symptoms and organ dysfunction.

Children with disseminated LCH (formerly called Letterer-Siwe disease) typically present before age 2 years with a seborrheic skin rash, fever, weight loss, lymphadenopathy, hepatosplenomegaly, and hematologic abnormalities.

Diagnosis is made with biopsy of the involved organ. The workup should include a CBC, liver and kidney function tests, a skeletal survey or technetium bone scan, and a urinalysis with specific gravity to rule out diabetes insipidus.

**Treatment & Prognosis**

The outcome in LCH is extremely variable, but the process usually resolves spontaneously. Isolated lesions may need no therapy at all. Intrallesional corticosteroids, curettage, and low-dose radiation therapy are useful local treatment measures for symptomatic focal lesions. Patients with localized disease have an excellent prognosis.

Multifocal disease is often treated with systemic chemotherapy. Prednisone with vinblastine or etoposide can be given repeatedly or continuously until lesions heal; the drugs can then be reduced and finally stopped. HSCT can also be used with success in refractory cases.

Multifocal disease is less predictable, but most cases resolve without sequelae. Age, degree of organ involvement, and response to therapy are the most important prognostic factors.
HEMATOPOIETIC STEM CELL TRANSPLANTATION

Amy K. Keating, MD, Roger H. Giller, MD, & Ralph R. Quinones, MD

INDICATIONS & RATIONALE

Hematopoietic stem cell transplantation (HSCT), often referred to as bone marrow transplantation, involves the intravenous infusion of stem cells to reestablish normal hematopoiesis following marrow ablative or subablative chemotherapy, or radiation therapy (or both). HSCT is considered standard therapy for a variety of malignancies, hematopoietic disorders (aplastic anemia, hemoglobinopathies), storage diseases, and severe immunodeficiencies. It is considered first-line therapy in illnesses such as JMML and severe combined immunodeficiency, as no other curative therapy exists, but most often it is recommended only in high-risk situations or when conventional treatment fails. For example, HSCT is used in sickle cell disease for patients with significant complications and in leukemia patients who have very high-risk cytogenetic features.

The rationale for HSCT in patients with nonmalignant disorders is that the transplanted stem cells replace the absent or defective hematopoietic or lymphoid elements. In patients with storage disorders, such as Hurler disease, HSCT provides enzyme-making donor macrophages that populate host tissues.

In children with oncologic disorders, HSCT is multidimensional. Because marrow function is rescued with hematopoietic stem cells, higher doses of chemotherapy or radiation (or both) can be administered, which may overcome cancer cell resistance and achieve optimal tumor cell kill. Additionally, in patients who receive an allogeneic HSCT (stem cells from another person), the donor lymphoid cells may recognize the cancer as foreign and provide an immunologic attack on the malignancy, a concept known as the graft-versus-tumor (GVT) effect.

PREPARATION FOR HSCT

The selection of the stem cell source for transplantation is an important first step. There are a variety of stem cell sources to consider, and their utility is dependent on the disease process. HSCT sources can be divided into two main categories: autologous (ie, infusion of the patient’s own hematopoietic stem cells) and allogeneic (ie, infusion of another individual’s hematopoietic stem cells). Stem cells can be obtained from bone marrow, peripheral blood, or umbilical cord blood.

Autologous transplantation, often referred to as “stem cell rescue” is restricted to the treatment of selected pediatric malignancies, such as neuroblastoma, lymphoma, certain brain tumors, and Ewing sarcoma. Autologous transplantation offers the ability to deliver large doses of chemotherapy followed by hematopoietic rescue using an infusion of the patients own stem cells. Relapse of the original disease continues to be the greatest obstacle to successful autologous transplantation, likely due to limitations in achieving systemic cancer control prior to transplant, collecting sufficient progenitor cells that are not contaminated by tumor cells, and lack of GVT effect.

The selection of a suitable donor for allogeneic transplantation is critical and remains a major challenge. The principle genes known to encode for allogeneic recognition reside within the major histocompatibility complex (MHC) located on chromosome 6. The MHC class I antigens, HLA-A, HLA-B, and HLA-C, and the class II antigens, HLA-DR and HLA-DQ, can mediate graft rejection or graft-versus-host disease (GVHD). Each child expresses one set of paternal and one set of maternal HLA antigens. Thus, the probability of one child inheriting any specific combination and matching another sibling for an allogeneic transplant is 1 in 4. Large worldwide registries for bone marrow and umbilical cord blood donors have been developed; however, finding a closely matched unrelated donor can still be difficult, especially in underrepresented minority populations.

TRANSPLANT FUNDAMENTALS

Transplantation has four major treatment phases: preparative therapy, lymphohematopoietic rescue, supportive care, and long-term follow-up. The preparative phase is designed to be both myeloablative and antineoplastic. In the allogeneic transplant recipient, the preparative treatment also provides the
necessary immunosuppression for successful donor engraftment. Preparative regimens use one or more chemotherapy drugs, often in combination with total body irradiation.

Lymphohematopoietic rescue is accomplished by the intravenous infusion of bone marrow, peripheral blood progenitor cells, or umbilical cord blood. Graft failure after allogeneic transplantation is rare in patients receiving stem cells from genotypically identical related donors but may be as high as 5–15% if the donor and patient are mismatched or unrelated. In allogeneic transplantation, marrow processing prior to infusion may include removal of contaminating RBCs for ABO incompatibility or T-cell depletion to reduce the risk of GVHD. In autologous transplantation, tumor purging or stem cell enrichment procedures can be performed for selected indications.

Supportive care in the initial months after transplantation includes transfusions, infection prophylaxis and treatment, and nutritional support. Immunosuppression for GVHD prophylaxis is necessary in allogeneic transplants. All blood products should be leukocyte-depleted to prevent the risk of CMV transmission. In addition, blood products must be irradiated to prevent GVHD from contaminating lymphocytes that remain even in leukocyte reduced blood products.

Successful engraftment usually occurs 10–28 days following transplantation. Peripheral blood stem cell transplant patients usually recover neutrophil counts earlier than patients receiving bone marrow or cord blood transplants. Platelet recovery generally occurs 6 or more weeks after HSCT. Hematopoietic growth factors such as granulocyte colony-stimulating factor may be used to hasten myeloid recovery.

**INFECTIOUS COMPLICATIONS**

Infections from bacteria, viruses, fungi, and protozoa account for significant morbidity and mortality in HSCT patients. Certain infections are typically seen at different time intervals after transplantation. During the early phase (0–1 month after transplant), when profound neutropenia and mucosal disruption occur, bacteria from the patient’s aerodigestive tract are common culprits in bacteremia. Empiric antibiotic coverage and intravenous immune globulin decrease the risk of bacterial sepsis immediately following transplant. The presence of central venous catheters makes antibiotic coverage against gram-positive bacteria an important consideration in infection management. Reactivation of herpes simplex virus may occur in as many as 70% of seropositive patients; thus, acyclovir prophylaxis is commonly employed. Fungal infections, particularly with *Candida* and *Aspergillus*, have made antifungal prophylaxis routine.

In the intermediate post-HSCT phase (1–6 months after transplant), the patient often has reduced T-lymphocyte numbers and function and thus is susceptible to viral pathogens, including CMV from endogenous reactivation, as well as common viruses found in the general population. The heightened potential of community acquired viral pathogens, such as respiratory syncytial virus, adenovirus, influenza, parainfluenza, and human metapneumovirus, to result in life-threatening illness in HSCT recipients is critical to recognize. Reducing acquisition of these infections through careful handwashing and contact restriction is important until immune competence returns. If infection develops, prompt diagnosis and use of available antiviral therapies, such as intrahed ribavirin, can be lifesaving. Prophylactic administration of acyclovir or ganciclovir helps limit CMV and other herpesvirus (herpes simplex virus, varicella-zoster virus) infections. Protozoal infections such as *Pneumocystis jiroveci* pneumonia, also a risk in this intermediate phase, can be prevented by prophylaxis with trimethoprim–sulfamethoxazole, dapsone, or pentamidine.

The late phase (6–12 months after transplant), is characterized by infections from encapsulated bacteria such as *Pneumococcus* due to dysfunction of the reticuloendothelial system. Reactivation of varicella-zoster virus as shingles is also common. Patients on prolonged immunosuppressive treatment for chronic GVHD have increased and protracted risk of all types of infections.

**GRAFT-VERSUS-HOST DISEASE**

Despite the use of immunosuppressive agents, anti–T-cell antibodies, and T-cell depletion of the donor graft, approximately 20–70% of allogeneic HSCT patients experience some degree of acute GVHD. Factors influencing GVHD risk include the degree of HLA match, stem cell source, patient age, and donor sex. Acute GVHD occurs within the first 100 days after transplantation. The first manifestation typically is a maculopapular skin rash. Skin biopsies may be done to confirm the diagnosis. Intestinal involvement results in secretory diarrhea, and hepatic involvement leads to cholestatic jaundice. Chronic GVHD occurs after day 100 and may involve multiple organ systems. Sclerotic skin, malabsorption, weight loss, keratoconjunctivitis sicca, oral mucositis, chronic lung disease, and cholestatic jaundice are common manifestations. Treatment of GVHD consists of further use of immunosuppressive agents.

**LONG-TERM COMPLICATIONS**

Long-term follow-up of HSCT patients is essential. Patients are at risk for numerous complications, including pulmonary disease, cataracts, endocrine dysfunction affecting growth and fertility, cardiac dysfunction, avascular necrosis of bone, developmental delay, and secondary malignancies.

Although HSCT has many challenges, it represents an important advance in curative treatment for a variety of serious pediatric illnesses.

Late effects of treatment by surgery, radiation, and chemotherapy have been identified in survivors of pediatric cancer. Current estimates are that 1 in every 900 adults younger than age 45 years is a pediatric cancer survivor. One recent study found that 60% of survivors of pediatric cancer diagnosed between 1970 and 1986 have at least one chronic condition. Virtually any organ system can demonstrate sequelae related to previous cancer therapy. This has necessitated the creation of specialized oncology clinics whose function it is to identify and provide treatment to these patients.

The Childhood Cancer Survivor Study, a pediatric multi-institutional collaborative project, was designed to investigate the various aspects of late effects of pediatric cancer therapy in a cohort of over 14,000 survivors of childhood cancer.

GROWTH COMPLICATIONS

Children who have received cranial irradiation are at highest risk of developing growth complications. Growth complications of cancer therapy in the pediatric survivor are generally secondary to direct damage to the pituitary gland, resulting in growth hormone deficiency. However, new evidence in children treated for ALL suggests that chemotherapy alone may result in an attenuation of linear growth without evidence of catch-up growth once therapy is discontinued. Up to 90% of patients who receive more than 30 Gy of radiation to the CNS will show evidence of growth hormone deficiency within 2 years. Approximately 50% of children receiving 24 Gy will have growth hormone problems. The effects of cranial irradiation appear to be age-related, with children younger than age 5 years at the time of therapy being particularly vulnerable. These patients usually benefit from growth hormone therapy. Currently, there is no evidence that such therapy causes a recurrence of cancer.

Spinal irradiation inhibits vertebral body growth. In 30% of treated children, standing heights may be less than the fifth percentile. Asymmetrical exposure of the spine to radiation may result in scoliosis.

Growth should be monitored closely, particularly in young survivors of childhood cancer. Follow-up studies should include height, weight, growth velocity, scoliosis examination, and, when indicated, growth hormone testing.

ENDOCRINE COMPLICATIONS

Thyroid dysfunction, manifesting as hypothyroidism, is common in children who received total body irradiation, cranial irradiation, or local radiation therapy to the neck. Particularly at risk are children with brain tumors who received more than 3000 cGy and those who received more than 4000 cGy to the neck region. The average time to develop thyroid dysfunction is 12 months after exposure, but the range is wide. Therefore, individuals at risk should be monitored yearly for at least 7 years from the completion of therapy. Although signs and symptoms of hypothyroidism may be present, most patients will have a normal thyroxine level with an elevated thyroid-stimulating hormone level. These individuals should be given thyroid hormone replacement because persistent stimulation of the thyroid from an elevated thyroid-stimulating hormone level may predispose to thyroid nodules and carcinomas. In a recent report from the Childhood Cancer Survivor Study, thyroid cancer occurred at 18 times the expected rate for the general population in pediatric cancer survivors who received radiation to the neck region. Hyperthyroidism, although rare, also occurs in patients who have received neck irradiation.

Precocious puberty, delayed puberty, and infertility are all potential consequences of cancer therapy. Precocious puberty, more common in girls, is usually a result of cranial irradiation causing premature activation of the hypothalamic-pituitary axis. This results in premature closure of the epiphysis and decreased adult height. Luteinizing hormone analogue and growth hormone are used to halt early puberty and facilitate continued growth.

Gonadal dysfunction in males is usually the result of radiation to the testes. Patients who receive testicular irradiation as part of their therapy for ALL, abdominal irradiation for Hodgkin disease, or total body irradiation for HSCT are at highest risk. Radiation damages both the germinal epithelium (producing azoospermia) and Leydig cells (causing low testosterone levels and delayed puberty). Alkylating agents such as ifosfamide and cyclophosphamide can also interfere with male gonadal function, resulting in oligosperma or azoospermia, low testosterone levels, and abnormal follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels. Determination of testicular size, semen analysis, and measurement of testosterone, FSH, and LH levels will help identify abnormalities in patients at risk. When therapy is expected to result in gonadal dysfunction, pretherapy sperm banking should be offered to adolescent males.

Exposure of the ovaries to abdominal radiation may result in delayed puberty with a resultant increase in FSH and LH and a decrease in estrogen. Girls receiving total body irradiation as preparation for HSCT and those receiving craniospinal irradiation are at particularly high risk for delayed puberty as well as premature menopause. In patients at high risk for development of gonadal complications, a detailed menstrual history should be obtained, and LH, FSH, and estrogen levels should be monitored if indicated.

No studies to date have confirmed an increased risk of spontaneous abortions, stillbirths, premature births, congenital malformations, or genetic diseases in the offspring of
childhood cancer survivors. Women who have received abdominal irradiation may develop uterine vascular insufficiency or fibrosis of the abdominal and pelvic musculature or uterus, and their pregnancies should be considered high-risk.

**CARDIOPULMONARY COMPLICATIONS**

Pulmonary dysfunction generally manifests as pulmonary fibrosis. Therapy-related factors known to cause pulmonary toxicities include certain chemotherapeutic agents, such as bleomycin, the nitrosoureas, and busulfan, as well as lung or total body irradiation. Pulmonary toxicity due to chemotherapy is related to the total cumulative dose received. Pulmonary function tests in patients with therapy-induced toxicity show restrictive lung disease, with decreased carbon monoxide diffusion and small lung volumes. Individuals exposed to these risk factors should be counseled to refrain from smoking and to give proper notification of the treatment history if they should require general anesthesia.

Cardiac complications usually result from exposure to anthracyclines (daunorubicin, doxorubicin, and mitoxantrone), which destroy myocytes and lead to inadequate myocardial growth as the child ages, and eventually result in congestive heart failure. The incidence of anthracycline cardiomyopathy increases in a dose-dependent fashion. At least 5% of patients who have received a cumulative dose of more than 550 mg/m² of anthracyclines experience cardiac dysfunction. In a recent study, complications from these agents appeared 6–19 years following administration of the drugs. Pregnant women who have received anthracyclines should be followed closely for signs and symptoms of congestive heart failure, as peripartum cardiomyopathy has been reported.

Radiation therapy to the mediastinal region, which is a common component of therapy for Hodgkin disease, has been linked to an increased risk of coronary artery disease; chronic restrictive pericarditis may also occur in these patients.

Current recommendations include an exercise echocardiogram and electrocardiogram every 1–5 years, depending on the age at therapy, total cumulative dose received, and presence or absence of mediastinal irradiation. Selective monitoring with various modalities is indicated for those who were treated with anthracyclines when they were younger than age 4 years or received more than 500 mg/m² of these drugs. Measurement of serum levels of cardiac troponin-T or atrial natriuretic peptide may be useful in assessing early cardiotoxicity of anthracyclines.

**RENA L COM P LICATIONS**

Long-term renal side effects stem from therapy with cisplatin, alkylating agents (ifosfamide and cyclophosphamide), or pelvic irradiation. Patients who have received cisplatin may develop abnormal creatinine clearance, which may or may not be accompanied by abnormal serum creatinine levels, as well as persistent tubular dysfunction with hypomagnesemia. Alkylating agents can cause hemorrhagic cystitis, which may continue after chemotherapy has been terminated and has been associated with the development of bladder carcinoma. Ifosfamide can also cause Fanconi syndrome, which may result in clinical rickets if adequate phosphate replacement is not provided. Pelvic irradiation may result in abnormal bladder function with dribbling, frequency, and enuresis.

Patients seen in long-term follow-up who have received nephrotoxic agents should be monitored with urinalysis, appropriate electrolyte profiles, and blood pressure. Urine collection for creatinine clearance or renal ultrasound may be indicated in individuals with suspected renal toxicity.

**NEUROPSYCHOLOGICAL COMPLICATIONS**

Pediatric cancer survivors who have received cranial irradiation for ALL or brain tumors appear to be at greatest risk for neuropsychological sequelae. The severity of cranial irradiation effects varies among individual patients and depends on the dose and dose schedule, the size and location of the radiation field, the amount of time elapsed after treatment, the child’s age at therapy, and the child’s gender. Girls may be more susceptible than boys to CNS toxicity because of more rapid brain growth and development during childhood.

The main effects of CNS irradiation appear to be related to attention capacities, ability with nonverbal tasks and mathematics, and short-term memory. Recent studies support the association between treatment with high-dose systemic methotrexate, triple intrathecal chemotherapy, and, more recently, dexamethasone and more significant cognitive impairment.

Additionally, pediatric cancer patients have been reported as having more behavior problems and as being less socially competent than a sibling control group. Adolescent survivors of cancer demonstrate an increased sense of physical fragility and vulnerability manifested as hypochondriasis or phobic behaviors.

Finally, childhood cancer survivors are more likely to report symptoms of depression and somatic distress in adulthood. Pediatric cancer survivors may require ongoing counseling or other psychological interventions once they have completed therapy.

**SECOND MALIGNANCIES**

Approximately 3–12% of children receiving cancer treatment will develop a new cancer within 20 years of their first diagnosis. This is a tenfold increased incidence when compared with age-matched control subjects. Particular risk factors include exposure to alkylating agents, epipodophyllotoxins (VP-16), and radiation therapy, primary diagnosis of retinoblastoma or Hodgkin disease, or the presence of an inherited genetic susceptibility syndrome (Li-Fraumeni syn-
drome or NF). In a recent report, the cumulative estimated incidence of second malignant neoplasms for the cohort of the Childhood Cancer Survivor Study was 3.2% at 20 years from diagnosis.

Second hematopoietic malignancies (acute myelogenous leukemia) occur as a result of therapy with epipodophyllotoxins or alkylating agents. It is unclear whether the schedule of drug administration and the total dose are related to the development of this secondary leukemia.

Children receiving radiation therapy are at risk for developing second malignancies, such as sarcomas, carcinomas, or brain tumors, in the field of radiation. A recent report examining the incidence of second neoplasms in a cohort of pediatric Hodgkin disease patients showed the cumulative risk of a second neoplasm to be as high as 8% at 15 years from diagnosis. The most common solid tumor was breast cancer (the majority located within the radiation field) followed by thyroid cancer. Girls aged 10–16 years when they received radiation therapy were at highest risk and had an actuarial incidence that approached 35% by age 40 years.

Children experience pain to at least the same level as adults. Multiple studies have shown that neonates and infants perceive pain and remember these painful experiences. Frequently, opioid and nonopioid analgesics are underprescribed and underdosed in children owing to excessive concerns about respiratory depression or incomplete understanding of the need for pain medications in children, or both. Few data are available to guide the dosing of many pain medications, and the majority of pain medications available on the market today are unlabeled for use in pediatric patients.

PAIN MANAGEMENT

PAIN ASSESSMENT

Pain Scales

Standardizing pain measurements requires the use of appropriate pain scales. At most institutions, pain scales are stratified by age (Table 30–1) and are used throughout the institution from operating room to medical floor to clinic, creating a common language around a patient’s pain. Pain assessment using such scales has become the “fifth vital sign” in hospital settings and is documented at least as frequently as heart rate and blood pressure at many pediatric centers around the world. Many pain scales are available (see Figures 30–1 and 30–2, and Table 30–2, for examples). The type of scale used is less important than its use on a consistent basis.

Special Populations

Noncommunicative patients such as neonates and the cognitively impaired are often difficult to assess for pain. In these patient populations, use of an appropriate assessment tool (see Table 30–1) on a frequent basis is essential to assure adequate pain control. An increasing pain score trend is often a sign of discomfort.

ACUTE PAIN

General Considerations

Acute pain is caused by an identifiable source. In most cases it is self-limiting, and treatment is a reflection of severity and type of injury. In children the majority of acute pain is caused by trauma or, if in a hospital setting, an iatrogenic source such as surgery.

Treatment

Treatment of acute pain depends on the disposition of the individual patient. For outpatient care the mainstay of treatment is nonsteroidal anti-inflammatory drugs (NSAIDs; Table 30–3). Acetaminophen is the most commonly used NSAID. Acetaminophen is administered via oral or rectal routes but is more predictable in its effects as an oral dose. Round-the-clock administration has been proved to be more effective than as-needed (PRN) dosing for minor pain or as an adjunct for major pain. The toxicity of acetaminophen is low in clinically used doses; however, liver damage or failure can occur with doses exceeding 200 mg/kg/d. Other oral analgesics available in suspension are ibuprofen and naproxen (see Table 30–3 for dosing).

When pain is more severe oral opioids can be added for short-term use (Table 30–4). Many of these drugs are formulated with an NSAID, for example, oxycodone plus acetaminophen (Percocet) and hydrocodone plus acetaminophen (Lortab). When using combination drugs, the dose of drug is based on the opioid component. Other concomitantly administered similar NSAIDs should be discontinued. The most commonly used oral opioids are oxycodone, hydrocodone, and codeine. Codeine is the least recommended because of its metabolism, which involves conversion of the
parent drug to morphine via the cytochrome P-450 2D6 isoenzyme. Between 1% and 10% of people (Asians, 1–2%; African Americans, 1–3%; Caucasians, 5–10%) have a genetic polymorphism that makes them poor metabolizers of codeine. These patients obtain no effect from this drug. A very small percentage of patients (primarily from East Africa) are ultrarapid metabolizers. These patients convert 10–15 times the amount of parent drug to the active compound, which can result in clinical toxicity. Morphine, oxycodone, and hydrocodone are all available as suspensions, are active as administered, and are metabolized by multiple routes.

For severe pain not amenable to oral analgesics, an intravenous opioid can be titrated to effect; options for pain relief are dependent on the severity and location of pain, and the patient’s age. Often the NSAID ketorolac (0.5–1.0 mg/kg) is used as an adjunct for severe pain. Side effects of ketorolac are the same as for adults: renal insufficiency, gastric irritability and prolonged bleeding times due to decreased platelet adhesiveness. Patients with bleeding concerns should not receive ketorolac.

Patient-controlled analgesia (PCA) pumps can be used in children as young as age 6 years with proper instruction and coaching (Table 30–5). Morphine and hydromorphone are the most commonly used drugs for PCA management in the United States. Whenever PCA is used it is imperative to assess patients frequently (at least hourly) to assure adequate pain relief.

### CHRONIC PAIN

#### General Considerations

Chronic pain is pain that persists past the usual course of an acute illness or beyond the time that is expected for an acute injury. In children this is an increasingly recognized problem; it is estimated that chronic pain may affect up to 10–15% of children in the United States. Among the conditions commonly producing chronic pain in children are headache, abdominal pain, myofascial pain, fibromyalgia, juvenile rheumatoid arthritis, complex regional pain syndrome, phantom limb pain, and pain associated with cancer. Multiple contributing factors, including psychosocial issues and family dynamics, often contribute to chronic pain in children. Associating pain with a single physical cause can lead the physician to order repeated invasive laboratory and diagnostic tests.

| Table 30–1. Commonly used pain scales and their age-appropriate use. |
|------------------|------------------|------------------|------------------|
| Scale            | Type             | Description                   | Age Group            |
| Numeric          | Self-report      | 0–10 scale; 0 = no pain, 10 = worst pain you could ever imagine | Children who understand the concept of numbers, rank, and order; generally > 8 y |
| Bieri and Wong-Baker scales | Self-report | 6 faces that range from no pain to the worst pain you can imagine (see Figures 30–1 and 30–2) | Younger children who have difficulty with numeric scale; cognitive age 3–7 y |
| FLACC            | Behavioral observer | 5 categories: face, legs, activity, cry, and consolability; range of total score is 0–10; score ≥ 7 is severe pain (see Table 30–2) | Nonverbal children > 1 y |
| CRIES, NIPS, PIPP | Behavioral observer | Rates a set of standard criteria and gives a score | Nonverbal infant < 1 y |

\*FLACC is an acronym derived from the categories assessed by the scale: face, legs, activity, cry, consolability.

\*CRIES is an acronym for Crying Requires O2 saturation, Increased vital signs, Expression and Sleeplessness.

NIPS, Neonatal Infant Pain Scale; PIPP, Premature Infant Pain Profile.

▲ Figure 30–1. Bieri Faces Pain Scale, revised. (Reproduced, with permission, from Bieri D et al: The Faces Pain Scale for the self-assessment of the severity of pain experienced by children: Development, initial validation, and preliminary investigation for ratio scale properties. Pain 1990;41:139.)
and to overprescribe medications. A multidimensional assessment to chronic pain is optimal and often required.

### Treatment

A multidisciplinary team approach is standard of care for treating chronic pain in children. All children evaluated for chronic pain should be seen on their initial visit by all primary members of the team to establish a management strategy. Team members should include a physician specializing in pain management, a pediatric psychologist or psychiatrist (or both), occupational and physical therapists, advanced pain nurses (APNs), and a social worker. The majority of pediatric chronic pain management programs in the United States base their approach on combined intensive rehabilitation and intensive psychotherapy, relying minimally on invasive procedures and pharmacotherapy.

#### A. Tolerance, Dependence, and Addiction

Adults and children are similar in their physiologic and psychological responses to opioids. A consensus paper by the American Academy of Pain Medicine, American Pain Society, and American Society of Addiction Medicine defined important differences between normal and pathologic responses to opioids. The definitions of tolerance, dependence, and addiction are listed below.

1. **Tolerance**—A state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug’s effects over time. Tolerance develops at different rates for different opioid effects (ie, tolerance develops to sleepiness and respiratory depression before it develops to constipation and analgesia).

2. **Dependence**—A state of adaptation manifested by a drug class-specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, or decreasing blood level of the drug; by administration of an antagonist; or by a combination of these actions.

*FLACC is an acronym derived from the categories assessed by the scale: face, legs, activity, cry, consolability.*
3. Addiction—A primary, chronic, neurobiologic disease, the development and manifestations of which are influenced by genetic, psychosocial, and environmental factors. Addiction is characterized by behaviors that include one or more of the following (the 3 Cs):

- Loss of Control over use of drug
- Craving and compulsive use of drug
- Use despite adverse consequences

Addiction is rare when opioids are used appropriately for acute pain in inpatient and outpatient settings. It should be emphasized that tolerance and dependence are not synonymous with addiction.

Heit HA: Addiction, physical dependence, and tolerance: Precise definitions to help clinicians evaluate and treat chronic pain patients. J Pain Palliat Care Pharmacother 2003;17:15 [PMID: 14640337].

B. Withdrawal

1. Recognition—Withdrawal symptoms can be expected to occur for all patients after 1 week of opioid treatment. Signs of withdrawal in older children include agitation, irritability, dysphoria, tachycardia, tachypnea, nasal congestion, temperature instability, and feeding intolerance. In neonates with withdrawal (neonatal abstinence syndrome), common symptoms include neurologic excitability, gastrointestinal dysfunction, autonomic signs (increased sweating, nasal stuffiness, fever, mottling, poor weight gain), and skin excoriations caused by excessive rubbing.

2. Treatment protocol—To minimize withdrawal symptoms in patients being weaned from opioid medications, clinicians should devise a schedule for dose reduction in conjunction with the patient and family. The duration of opioid therapy must be taken into consideration. Standard protocols involve switching to an opioid that can be administered once a day (eg, methadone) and decreasing the dose by 10–25% every 1–2 days. The patient should be monitored for signs of withdrawal over this period. If symptoms develop, consider lorazepam, 0.05–0.1 mg/kg every 6–8 hours or a clonidine patch, 0.1 mg/d (changed every fifth day).

PEDIATRIC PALLIATIVE & END-OF-LIFE CARE

It has been estimated that almost 55,000 children die each year in the United States. At least half of these children die during the newborn period or within the first year of life. Many of these children, particularly those older than 1 year of age, suffer from illnesses that are clearly life-limiting. Thousands more are diagnosed with life-limiting illnesses resulting in chronic conditions that may last for many years, even decades. Children who are diagnosed with life-threatening illnesses that may be curable (eg, cancer) continue to live with the potential of a recurrence of their malignancy for many years. In all of these populations palliative and end-of-life care can play an important role during patients’ illnesses.

Although commonly used interchangeably, palliative care and end-of-life care are not synonymous terms. Palliative care aims to prevent, relieve, reduce, or soothe the symptoms produced by potential life-limiting illnesses or their treatments and to maintain the patient’s quality of life along the entire continuum of treatment. Provision of palliative care does not imply imminent death nor does it prohibit aggressive curative treatment modalities. Rather, it acknowledges the uncertainty and potential for suffering inherent in a potentially life-limiting condition such as cancer. Understanding how a family defines quality of life and suffering for their child is imperative and provides a framework for decision making between care providers and the family throughout treatment.

While a child is responding well to treatment, the primary focus is on achieving cure of the disease. Palliative care

goals at this time focus on promoting quality of life in preparation for survivorship in the face of a potentially life-limiting illness. Some of these goals include helping a family come to terms with the diagnosis, addressing issues of treatment-related pain and distress, facilitating reintegration into the social realms of school and community, and promoting as much normalcy in the child’s life as possible. When it becomes clear that the chances for cure are poor or present an unreasonable cost to the child’s quality of life, the goals of palliative care shift. The focus is still on promoting quality of life but now in preparation for a comfortable and dignified end of life with increasingly less attention given to the treatment or cure of the disease itself.

Palliative care not only comprises support in the pain and symptom management of the disease but also addresses equally the psychosocial, emotional, and spiritual needs of patients with a potential life-limiting illness and their family.

**CHILDREN WHO MAY BENEFIT FROM PALLIATIVE CARE**

Four groups of conditions have been identified for which palliative care is appropriate:

1. Conditions for which curative treatment is possible but may fail, such as advanced or progressive cancer and complex and severe congenital or acquired heart disease.
2. Conditions requiring intensive long-term treatment aimed at maintaining the quality of life such as HIV/AIDS, cystic fibrosis, and muscular dystrophy.
3. Progressive conditions in which treatment is exclusively palliative after diagnosis, such as progressive metabolic disorders and certain chromosomal abnormalities.
4. Conditions involving severe, nonprogressive disability, causing extreme vulnerability to health complications, such as severe cerebral palsy and anoxic brain injury.

ER, extended release; IR, immediate release; IV, intravenous; PO, by mouth (orally).
Optimal pain management is critical when providing pediatric palliative care. (See the section on Pain Management, earlier, for definitions and guidelines for treatment.) Children who are opioid-naïve will usually respond very well to conventional dosing of narcotics. Children who have been receiving a long-term narcotic such as codeine for pain management may need a dosage at the higher end of the spectrum when switching to an opioid such as morphine. Adjunctive medications such as NSAIDs can be extremely helpful as well and may help reduce the frequency of narcotic dose escalations. However, children at the end of life may need ongoing upward dose adjustments, which at times may exceed normal dose recommendations. When given with the intent to achieve comfort in the dying child, these escalations are ethically and morally appropriate.

### QUALITY-OF-LIFE ADJUNCTS & SYMPTOM MANAGEMENT

Certain nonpain symptoms and signs may develop more quickly in children at the end of life as compared with the adult population. A thorough and complete history and physical examination should be obtained. It is critical to determine how much distress the symptom causes the child and how much it interferes with the child’s and family’s routine. Areas of management should include pharmacologic intervention, nursing care, and psychosocial support. Symptoms that commonly occur during disease progression and at the end of life in children with a life-limiting condition are listed in Table 30–6, along with suggestions for management.

### SPIRITUAL & CULTURAL SUPPORT

Health care decisions are often intertwined with a family’s culture and belief system. Understanding the influences of a family’s beliefs and culture allows the practitioner to provide sensitive, appropriate care, particularly at the end of life. Interaction with members of the family’s faith and cultural communities can often be instrumental in helping both the care team and the community support of the family. Allowance for specific prayers, rituals, or other activities may help facilitate procedures and discussions.

Families who speak a foreign language are at risk for inadequate support. They may have fewer opportunities to express their concerns and fears, ask questions, and validate their understanding due to language and cultural constraints. Every effort should be made to find and utilize a qualified interpreter, particularly for any discussion that involves delivering difficult news or making critical decisions. Many times, the role of interpreter is imposed on a bilingual family member or friend who may not understand
medical terminology well enough to translate clearly or who may deliberately translate the information inaccurately in an attempt to protect the family.

**ADVANCE CARE PLANNING**

Advance care planning allows patients and families to make known their wishes about what to do in care of serious or life-threatening problems. Advance care planning has been described as a four-step process. First, individuals considered decision makers are identified and included in the process. Second, an assessment of the patient’s and family’s understanding of the illness and prognosis is made and the impending death is described in terms the child and family can understand. Third, on the basis of their understanding of the illness and prognosis, the goals of care are determined regarding current and future intervention—curative, uncertain, or primarily focused on providing comfort. Finally, shared decisions about the current and future use or abandonment of life-sustaining techniques and aggressive medical interventions are made. If a disagreement exists between parents or between parents and patient regarding these techniques or interventions, it may be prudent to involve the hospital’s ethics committee to aid in resolving these issues.

Some states permit parents to sign an advanced directive that asserts their decision not to have resuscitative attempts made in the event of a cardiac or respiratory arrest outside of the hospital. When an advanced directive is in place, emergency responders are not required to provide cardiopulmonary resuscitation if called to the scene. Some school districts will respect an advanced directive on school property, many will not. If a child with an advanced directive in place wishes to attend school, a discussion between the medical team and school officials should be arranged to determine the best plan should the child have a cardiac or respiratory arrest at school.

Parents, and occasionally the child, may bring up the possibility of donating organs or body tissues after death. Although the tissues that may be donated by a child may be limited in some instances by the type of disease (eg, cancer), some parents find immense comfort in knowing their child was able to

benefit another. If the parents have not discussed donation with the physician by the time of death and donation is possible, the physician should offer the opportunity to the family.

Autopsy is another subject many physicians find difficult to approach with a family, but it is an important option to discuss. In cases of anticipated death from natural causes, autopsies are generally not mandatory; however, information obtained from an autopsy may be useful for parental peace of mind or medical research. If death at home is to be followed by an autopsy, special arrangements for transporting and receiving the body will need to be made with the mortuary or the coroner.

The immune deficiencies of childhood comprise numerous rare disorders that have been well characterized by a combination of clinical patterns, immunologic laboratory evidence, and often molecular identification of the mutant gene. Children with primary immunodeficiency (PID) commonly present with recurrent or severe infections, but most children with frequent minor infections (e.g., otitis media or sinusitis) do not have an underlying immune disorder. Immunodeficiency should be considered when infections are severe, persistent, resistant to standard treatment, or caused by opportunistic organisms. Clinical patterns and recurring infections with certain types of microbes are indicative of specific immune deficiencies. Because delay in the diagnosis of PIDs is common, heightened diagnostic suspicion is warranted.

Host immunity can be divided into four main groups for the purpose of categorizing PIDs: antibody immunity (B lymphocytes), combined immunity (T and B lymphocytes), phagocytic immunity (neutrophil or mononuclear cells), and complement (bactericidal proteins also involved in opsonization). Understanding the role each category plays in host defense allows critical evaluation for possible immunodeficiency as the cause of recurrent infections.

**IMMUNODEFICIENCY EVALUATION: PRIMARY CONSIDERATIONS**

Before evaluating for a defined primary immunodeficiency, consider conditions that increase susceptibility to infection, such as allergic rhinitis (causing sinusitis), cystic fibrosis (causing failure to thrive, pneumonia, and sinus disease), asthma (causing chronic cough and pneumonia), foreign bodies, and conditions that interfere with skin integrity. Also exclude common causes of secondary immunodeficiency such as HIV infection, malnutrition, drugs, and protein loss via gastroenteropathy or kidney disease. If a single site is involved, exclude anatomic defects and foreign bodies. Figure 31–1 outlines the approach to considering PIDs.

Key clinical patterns can indicate the likelihood of a PID, the category of immune impairment (Table 31–1), and sometimes the specific PID. The frequency and severity of infections can be helpful when considering a PID. The Modell Foundation warning signs for PID are found in Figure 31–2. Children who meet two or more of these signs should be screened for PID. Age at the onset of infections can be a helpful clue, as defects in different arms of the immune system will present at typical ages. For instance, defects of phagocytes and cellular immunity typically present during the first months of life, whereas maternal antibody protects infants with antibody deficiency for 3–6 months. The type of infections should guide initial investigation, as antibody, complement, and phagocyte defects predispose mainly to bacterial infections; but diarrhea, superficial candidiasis, opportunistic infections, and severe herpesvirus infections are more characteristic of T-lymphocyte immunodeficiency. Combined immunodeficiency syndromes will present with a combination of infections typical for B-lymphocyte and T-lymphocyte deficiencies. Table 31–1 classifies PID into four main host immunity categories based on differences in these revealing clinical parameters of age of onset, specific pathogens, affected organs, and other special features. Finally, male gender increases the likelihood of an X-linked PID, while consanguinity increases the likelihood of an autosomal recessive form of PID.

The level of laboratory investigation should be based on the clinical presentation and the suspected category of host immunity impairment. A complete blood count and quantitative immunoglobulin measurement will identify the majority of those with PID, as antibody deficiencies account for at least 50% of PIDs (Figure 31–3). Table 31–2 summarizes the approach to laboratory evaluation of PID.
Antibodies & Immunoglobulins

Initial laboratory screening for antibody deficiency measures serum immunoglobulins (IgG, IgM and IgA, but not IgD). The normal ranges of IgG, IgM, and IgA vary by age as the production by B lymphocytes matures (see Table 31–3 for normal ranges). Some patients may have normal immunoglobulin levels but do not make protective specific antibodies; other patients have abnormal immunoglobulin levels but make protective specific antibodies. When interpreting immunoglobulin concentrations, remember that infants have lower normal values compared with adults. Evaluation of specific antibodies includes isohemagglutinins, which are naturally occurring antibodies (except in patients with blood group AB) and are detectable by age 6 months. Additional testing options include tetanus, diphtheria, Haemophilus, rubella, and mumps antibody levels following immunization. Assessing antibody response to pneumococcal polysaccharide can be helpful in the face of repeated pneumococcal infections, but as a screening tool it is often difficult to interpret, as the normal immune response to unconjugated polysaccharide vaccines may be weak or difficult to measure. The gold standard is preimmunization and postimmunization titers, with at least a threefold increase in titers 3 weeks postimmunization. Obtaining T- and B-lymphocyte counts is recommended if an initial screen revealed very low immunoglobulin concentrations for all classes, as certain hypogammaglobulinemic syndromes have low levels of or absent B lymphocytes (such as X-linked Bruton agammaglobulinemia). Protein electrophoresis can help identify the monoclonal increases seen in the oligoclonal gammopathy of Epstein-Barr virus (EBV) infections in X-linked lymphoproliferative syndrome, and in heavy-chain diseases. Serum albumin should be measured in patients with hypogammaglobulinemia to exclude secondary deficiencies due to protein loss through bowel or kidneys. IgG or IgA subclass measurements may be abnormal in patients with varied immunodeficiency syndromes, but they are rarely helpful in an initial evaluation.

T Lymphocytes

Initial laboratory screening for T lymphocytes includes a complete blood cell count with differential to evaluate for a decreased absolute lymphocyte count (< 1000/μL). Delayed hypersensitivity skin tests (such as Candida, tetanus, or mumps) give good evidence for antigen-specific T-lymphocyte immunity, but a negative or anergic result is not helpful, as it may be due to young age, chronic illness, or poor test technique. Even T-lymphocyte deficiencies will often not manifest anergy until the impairment is severe (eg, AIDS). When T-lymphocyte abnormalities are
suspected, it is important to check for specific antibody production and absolute numbers of T and B lymphocytes and their subsets (including CD3, CD4, CD8, CD19/CD20, and CD16/CD56). Because proper B-lymphocyte function and antibody production is dependent on T-lymphocyte function, most T-lymphocyte deficiencies manifest as combined impairments. Tests of T-lymphocyte proliferation and cytokine production can be supportive for characterizing immunodeficiency detected by initial tests, but they are not useful screening tests for children with chronic illness, recurrent infections, or young age; additionally, borderline function is often interpreted based on clinical correlation.

**Phagocytic Immunity**

Initial laboratory screening should include an evaluation for neutropenia with a complete blood count and differen-
A blood smear can be done to exclude Howell-Jolly bodies of asplenia and to look for normal lysosomal granules in neutrophils. The respiratory burst and generation of bactericidal factors can be tested by nitroblue tetrazolium reduction, but this test has generally been replaced by assessment of reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity using flow cytometry (dihydrorhodamine flow cytometry assay). Leukocyte adhesion molecules are also screened by flow cytometry methods, although the difference in symptoms of suspected phagocyte defects should dictate which tests are used. Quantification of bacterial ingestion and microbicidal activity may be available.

Complement Pathways (Figure 31–4)

Deficiency of classic complement pathway components can be excluded by a normal hemolytic complement titer (CH50), for which the patient’s serum must be separated and frozen to −70°C within 30 minutes of collection to prevent autodegradation of complement components. Alternative complement pathway deficiencies are similarly identified by AH50. Measuring individual complement component levels is not necessary if both CH50 and AH50 are normal. If the CH50 and AH50 are both low, the deficiency must be in their shared terminal pathway (C3, C5, C6, C7, C8, or C9). If CH50 is low, but AH50 is normal, the deficiency must be C1, C4, or C2; if AH50 is low and CH50 is normal, the deficiency must be factor D or B or properdin.

Recurrent bacterial infections, typically encapsulated bacteria.

Low immunoglobulin levels (usually).

Inability to make specific antibody to vaccinations or infections.

**Antibody Deficiency Syndromes**

**Essentials of Diagnosis & Typical Features**

- Recurrent bacterial infections, typically encapsulated bacteria.

**Figure 31-4.** Complement proteins and laboratory test pathways.
mary immunodeficiencies. Table 31–4 outlines primary antibody deficiency syndromes, laboratory findings, and genetic inheritance in these disorders. Patients who are unable to make specific antibody to vaccinations or infections are candidates for replacement gamma globulin therapy (ie, intravenous immunoglobulin [IVIG]). In contrast, those with secondary or transient hypogammaglobulinemia (ie, low total serum IgG level) who are able to make specific antibodies generally do not need or benefit from replacement IVIG.

1. X-Linked Agammaglobulinemia

**Essentials of Diagnosis & Typical Features**
- Child presents with infections early, usually after age 4 months.
- Typical bacterial infections include *Haemophilus influenzae* and *Streptococcus pneumoniae*.
- Risk for severe enteroviral infections with vaccine strains of poliovirus.
- Failure to thrive and absent lymphoid tissue on examination.
- Very low levels of immunoglobulins and B lymphocytes.

**General Considerations**
Children with X-linked agammaglobulinemia (XLA) typically present with infections after 4 months of age, when maternally derived IgG levels have declined. XLA is caused by a mutation on the X chromosome that results in low to absent circulating B lymphocytes and affects male patients. Early detection and diagnosis allow lifesaving replacement therapy with IVIG to be started prior to a potentially life-threatening infection.

**Clinical Findings**

**A. Symptoms and Signs**
Infections are usually due to *H influenzae* and *S pneumoniae*, but deep tissue infections and arthritis due to *Ureaplasma* species also are seen. Antibody-deficient patients are also at risk for severe enterovirus infections with vaccine strains of poliovirus resulting in paralysis, and echoviruses causing chronic encephalitis. At presentation, male infants have scant or absent lymphoid tissue including tonsils, adenoids, and lymph nodes. A small proportion also has a history of poor growth.

**B. Laboratory Findings**
Most patients have low levels of or absent immunoglobulins (IgM, IgG, and IgA) and, despite a normal leukocyte count, have low numbers of or absent B lymphocytes. XLA accounts for 85% of congenital hypogammaglobulinemia and occurs in about 1:200,000 male births. It results from mutations in the gene encoding the B lymphocyte tyrosine kinase (BTK), which is important for B-lymphocyte maturation. A BTK mutation by molecular analysis confirms the diagnosis of XLA.

**Differential Diagnosis**
The differential diagnosis includes other causes of antibody deficiency as well as combined immunodeficiencies. Children with XLA are male and typically present at a young age with serious or recurrent bacterial infections, often with encapsulated species. Additionally, compared with other causes of antibody deficiency, XLA patients have the lowest or even absent numbers of B lymphocytes, but normal numbers of T lymphocytes. The normal T-lymphocyte number and function in XLA differ from findings in combined immunodeficiency. Additional causes of recurrent infections and low immunoglobulin levels include protein loss through renal or gastrointestinal disease, but patients with these disorders present with normal numbers of B lymphocytes and, typically, an isolated IgG deficiency.

**Treatment**
Current therapy is with lifelong replacement IgG. In addition to preventing infections, IVIG replacement usually results in resolution of inflammatory arthritis and improves growth. Because the severity of infections varies and antibiotics are widely used, diagnosis is often delayed for years, but XLA must be considered in males with recurrent infections regardless of severity.

2. Autosomal Recessive Congenital Agammaglobulinemia

**General Considerations**
Autosomal recessive congenital agammaglobulinemia is rare, accounting for less than 15% of all congenital hypogammaglobulinemia. It occurs in both male and female children and is caused by an abnormality in the immunoglobulin chain expressed on the surface of B lymphocytes. In the most common form, defects of the μ heavy-chain gene result in abnormal or absent IgM.

**Clinical Findings**

**A. Symptoms and Signs**
Children present with recurrent infections, but the infections tend to have a very early onset, typically before age 6 months. Infections are bacterial and include pneumonia, otitis, sinusitis, meningitis, cellulitis, and sepsis.

**B. Laboratory Findings**
Patients usually have low numbers of circulating B lymphocytes and low levels of or absent immunoglobulins. Specific
antibody function is poor. When diagnosis is suspected, detection of a mutation in the μ heavy chain can confirm the most common type. Additional mutations include mutations of the Igα molecule, the BLNK adaptor protein, and the λ5 surrogate light chain.

**Differential Diagnosis**

The differential diagnosis is similar that of XLA, and includes XLA for male patients.

**Treatment**

Treatment and prognosis are similar to those outlined for XLA.

### 3. Common Variable Immunodeficiency

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Recurrent infections, often with *Giardia lamblia* and *Campylobacter jejuni*.
- Decreased levels of IgG and IgA; poor specific antibody responses.
- Often associated with autoimmune diseases.

**General Considerations**

Common variable immunodeficiency (CVID) is a diagnosis of exclusion after other causes of hypogammaglobulinemia have been eliminated. Onset may be at any age, and the incidence approaches 1:30,000. Many cases are sporadic, but a small percentage of patients have autosomal dominant or recessive inheritance and some cases are associated with HL-DR/DQ alleles.

**Clinical Findings**

**A. Symptoms and Signs**

Patients have recurrent infections, most often of the sinopulmonary tract, but chronic gastrointestinal infections may manifest with recurrent diarrhea. Patients with CVID are at risk for developing bronchiectasis, autoimmune diseases (idiopathic thrombocytopenic purpura, autoimmune hemolytic anemia, rheumatoid arthritis, and inflammatory bowel disease), and malignancies (especially gastric carcinoma and lymphoma).

**B. Laboratory Findings**

Laboratory findings are variable but typically reveal low levels of IgG and IgA, normal numbers of B lymphocytes, low numbers of memory B lymphocytes (evaluated by flow cytometry), and abnormal specific antibody levels and responses. Some patients have evidence of T-lymphocyte
abnormalities as well. Chronic gastrointestinal tract infections are often due to *G. lamblia* or *C. jejuni*.

Although CVID is typically a diagnosis of exclusion, recent research has yielded multiple specific mutations that have previous been labeled simply as CVID. One example is a mutation in a member of the tumor necrosis factor receptor family, identified as transmembrane activator and calcium-modulator and cyclophilin ligand interactor (TACI), which mediates isotype switching in B lymphocytes. TACI mutations were recently found in 10–15% of patients with CVID, as well as in some relatives of CVID patients with IgA deficiency. The mutations appear to be autosomal dominant with variable penetrance of clinical immunodeficiency and disease.

#### Differential Diagnosis

When a patient presents with recurrent infections, low immunoglobulin levels, and potentially autoimmune symptoms, many different diagnoses must be considered, including other causes of low immunoglobulin levels (loss and abnormal production) and autoimmune diseases. CVID patients have normal numbers of B lymphocytes despite their poor specific antibody responses, which differentiates them from patients with XLA and autosomal recessive agammaglobulinemia. Patients with CVID also lack the specific mutations responsible for those disorders.

#### Treatment

Treatment includes lifelong replacement therapy with IgG and routine assessment for bronchiectasis, autoimmune disorders, and malignancies. Prognosis depends on time to diagnosis and implementation of IgG replacement therapy, and can be good. Other complications include B-cell hyperplasia in the gut that may be severe enough to resemble Crohn disease, and gastric atrophy with achlorhydria, sometimes followed by pernicious anemia. Lymphoreticular proliferation can occur after EBV infection and is not always malignant.

---

**4. Autosomal Recessive Hyper-IgM Immunodeficiency**

Autosomal recessive forms of hyper-IgM immunodeficiency differ from the X-linked form (see section on Other Combined Immunodeficiency Disorders, later), as affected patients have normal expression and function of CD40 ligand. Patients have mutations in activation-induced cytidine deaminase (AID) or uracil glycosylase (UNG). AID is required for B lymphocytes to switch from producing IgM to production of IgG, IgA, or IgE. UNG is also important for isotype class switching. The clinical presentation of AID- and UNG-deficient patients is less severe than that of X-linked hyper-IgM syndrome and also lacks opportunistic infections. Affected patients often have associated lymphoid hyperplasia compared with the paucity of lymphoid tissue seen in X-linked hyper-IgM syndrome. Treatment with IVIG replacement decreases infections and often normalizes IgG levels.

---

**5. Acquired Hypogammaglobulinemia**

Acquired forms of hypogammaglobulinemia are common and may develop at any age. Causes of secondary hypogammaglobulinemia (nephrotic syndrome and protein-losing enteropathy) should be excluded by measuring serum albumin. Generally, acquired forms are not treated with IVIG because, although immunoglobulin levels are low, antibody function is adequately protective. Morphologic disorders or associated syndromes may point to a specific diagnosis.

---

**6. Transient Hypogammaglobulinemia**

Serum IgG levels normally decrease during an infant’s first 4–5 months of life as maternal IgG acquired in utero is metabolized. Transient hypogammaglobulinemia represents a delay in the onset of immunoglobulin synthesis that results in a prolonged nadir. Symptomatic patients present with recurrent infections, including upper respiratory tract infections, otitis, and sinusitis. Diagnosis is suspected in infants with low levels of IgG and IgA (usually two standard deviations below normal for age), but normal levels of IgM and normal numbers of circulating B lymphocytes. Importantly, infants have normal specific antibody responses and T-lymphocyte function. Apart from appropriate antibiotics, no treatment is required. Infants with severe infection and hypogammaglobulinemia could be given IVIG replacement, but benefits and risk must be considered and this is rarely necessary. Recovery occurs between 18 and 30 months of age and the prognosis for affected infants is excellent provided infections are treated promptly and appropriately.

---

**7. Selective Immunoglobulin Deficiencies**

Selective IgA deficiency is the most common immune abnormality, found in approximately 1:700 persons. It is defined by a serum IgA level less than 7 mg/dL. Serum IgM, IgG, specific antibodies, and B- and T-lymphocyte numbers and function are normal. Most people with low serum IgA are
without symptoms, but when symptoms are present, they include upper respiratory tract infections or diarrhea (or both). Associations also exist with inflammatory bowel disease, allergic disease, asthma, and autoimmune disorders (thyroiditis, arthritis, vitiligo, thrombocytopenia, and diabetes). IgA is primarily effective in its secreted form on mucosal surfaces.

IgA replacement is currently not feasible. For the majority of symptomatic IgA-deficient patients, antibiotics and appropriate autoimmune therapies are sufficient, but some patients have been treated with IVIG replacement. Caution must be exercised, as IgA-deficient patients are at risk for developing anti-IgA antibodies with blood product exposure, and the administration of blood products can result in anaphylaxis. Therefore when blood products are needed, washed packed red blood cells and volume expanders without blood products are recommended.

The possibility that deficiency of an IgG subclass (ie, abnormally low serum IgG2, IgG3, or IgG4) might predispose to recurrent upper respiratory tract infections in patients with normal total serum immunoglobulin levels is not well established. Normally, IgG1 comprises over 60% of total IgG and IgG2 over 10%. IgG3 accounts for about 5%, and IgG4 may be undetectable in up to 20% of healthy persons. Additionally, serum levels are age-related. It has been difficult to establish a link between IgG subclass deficiencies and any consistent pattern of infections. IgG replacement should be reserved for patients with defects in specific antibody production, which is rarely seen in patients with selective IgA or IgG subclass deficiencies.

**Treatment of Hypogammaglobulinemia**

The mainstay of therapy for hypogammaglobulinemia is replacement IgG, but management of infections is also important. Additional treatment modalities have included the use of cytokine therapy such as interleukin (IL)-2, hormone replacement, and vitamin supplementation. Curative therapy with bone marrow transplantation (BMT) has been successful in patients with XLA. Gene therapy has been difficult to establish a link between IgG subclass deficiencies and any consistent pattern of infections. IgG replacement should be reserved for patients with defects in specific antibody production, which is rarely seen in patients with selective IgA or IgG subclass deficiencies.

**SEVERE COMBINED IMMUNODEFICIENCY DISEASES**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Onset in first year of life.
- Recurrent infections caused by bacteria, viruses, fungi, and opportunistic pathogens.
- Chronic diarrhea and failure to thrive.
- Absent lymphoid tissue.

**General Considerations**

Combined T- and B-lymphocyte diseases include severe combined immunodeficiency diseases (SCID) that encompass congenital diseases caused by different genetic mutations that result in severe deficiency of T and B lymphocytes. Despite differences in underlying mutations, affected patients present similarly, with recurrent infections caused by bacteria, viruses, fungi, and opportunistic pathogens. Additionally, patients often suffer from chronic diarrhea and failure to thrive. Without treatment, all patients with SCID typically die within the first years of life. SCID must be considered in the differential diagnosis in any infant with diarrhea and hypogammaglobulinemia.

**Clinical Findings**

**A. Symptoms and Signs**

Common presentations include persistent cough, tachypnea or hypoxia secondary to underlying Pneumocystis carinii infection, or persistent oral or diaper candidiasis. Physical examination is notable for a lack of lymphoid tissue including tonsils and lymph nodes. A chest radiograph usually demonstrates an absent thymic shadow.

**B. Laboratory Findings**

Laboratory evaluation often reveals lymphopenia and some degree of hypogammaglobulinemia. Occasionally, an infant with SCID will present with normal numbers of lymphocytes resulting from transfusion-related engraftment or maternal T-lymocyte engraftment via peripartum transfusion. Natural killer (NK) cells and B-lymphocyte numbers may be decreased,
normal, or elevated. Additionally, in-vitro lymphocyte assays show poor response to mitogens, and specific antibodies are absent. Antenatal diagnosis is possible. Once the diagnosis of SCID is suspected, genetic testing should be pursued to confirm the diagnosis and the mutation present for both prognostic and genetic counseling purposes. Nine genes with mutations that result in SCID have been described to date. Clinical presentation and treatment is generally similar. The variants of SCID can be organized by the presence or absence of specific lymphocytes, including T, B, and NK cells (Table 31–5).

Differential Diagnosis

The differential diagnosis of SCID includes other causes of recurrent and severe infections and abnormal immune responses, most notably HIV disease. Other causes of hypogammaglobulinemia or agammaglobulinemia may be considered but will be ruled out due to abnormal T-lymphocyte function. The infection spectrum and severity of presentation in children with SCID is more severe and of earlier onset than that seen with CVID. Symptoms of congenital abnormalities with combined immunodeficiency features are discussed later in this chapter (see section on Genetic Syndromes Associated with Immunodeficiency).

Treatment

When SCID is suspected, *Pneumocystis* prophylaxis with trimethoprim-sulfamethoxazole and replacement IgG therapy should be initiated. Patients with suspected SCID should only be transfused with irradiated blood products and should not receive any live vaccines. Confirmation of the diagnosis should include screening for SCID subtypes listed in Table 31–5. BMT offers the best possibility of cure, with use of a human leukocyte antigen (HLA)-matched sibling offering the highest chance of success. In affected patients without HLA-identical donors, T-lymphocyte-depleted HLA haploidentical grafts or umbilical cord stem cells are used. For most patients, myeloablation is not necessary as the patient is without T lymphocytes. Additionally, most patients do not require graft-versus-host disease (GVHD) prophylaxis unless the donor is unrelated. T-lymphocyte reconstitution takes approximately 4 months, but only about 50% of patients regain full B-lymphocyte function, with the majority requiring long-term IVIG replacement. For months post-transplantation, patients are susceptible to many serious infections and prophylaxis is usually continued. Additionally, any signs or symptoms of infection must be promptly investigated and aggressively treated. The highest rate of success is in the youngest patients prior to developing infections (> 95% survival), but overall rates of survival range from 50–100% depending on the underlying mutation. Regarding gene therapy, X-linked SCID has been treated with autologous bone marrow in which normal function was transduced to lymphocytes by retroviral gene transfer. Unfortunately, two patients developed leukemia due to insertion of the retroviral vector near an oncogene. At this time, safer vectors are being sought.

- , absent; +, present; AR, autosomal recessive; IL, interleukin; NK, natural killer; XLR, X-linked recessive.

1. X-Linked Severe Combined Immunodeficiency

X-linked SCID, the most common form (40%) of SCID, results from mutations in *IL2RG* (IL-2 receptor gene) that encodes the common γ chain. The γ-chain protein is shared by multiple cell surface receptors for cytokines that are essential for T-lymphocyte maturation, including IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. Within the first 3 months of life, male infants present with diarrhea, cough, and rash. Laboratory evaluation reveals low T-lymphocyte numbers, normal numbers of B lymphocytes (which do not produce functional antibody), and absent NK cells.

2. Adenosine Deaminase Deficiency

Adenosine deaminase deficiency (ADA) is an autosomal recessive form of SCID caused by absence of adenosine deaminase, which is important for removal of toxic metabolites formed in T lymphocytes, including adenosine, 2′ deoxyadenosine, and 2′O-methyldeoxoadenosine. Increased levels of these metabolites result in T-lymphocyte death. Subsequently, affected patients develop complete absence of T-lymphocyte function. ADA SCID is distinguished from other variants of SCID by the following findings: the most profound lymphopenia (< 500/mm³); skeletal abnormalities, including chondro-osseous dysplasia (flared costochondral junctions and bone-in-bone anomalies in vertebrae); and deficiency of all types of lymphocytes. Diagnosis is suspected in patients with profound lymphopenia and recurrent infections. The diagnosis is confirmed with a red blood cell assay for ADA activity. The genetic mutation is on chromosome 20q13.2–13.11. In addition to BMT, restoration of immune competence can occur in some patients with weekly infusions of polyethylene glycol–stabilized ADA enzyme conjugate. Gene therapy of stem cells with an ADA-incorporating retroviral vector has been successful, but the vector had oncogenic adverse effects. The development of safer vectors is yet to come.

3. Janus Kinase 3 Deficiency

Another form of autosomal recessive SCID is due to mutations in the gene encoding janus kinase 3, which is important for intracellular signaling through the common γ chain. The clinical presentation and lymphocyte phenotype most closely resembles X-linked SCID, with low T and NK lymphocytes, and elevated, nonfunctional B lymphocytes.

4. Interleukin-7-Receptor-Alpha-Chain Deficiency

IL-7-receptor-alpha-chain (IL-7Rα) deficiency SCID is transmitted by autosomal recessive inheritance. The IL-7 receptor is important for T-lymphocyte maturation and mutations result in low T-lymphocyte numbers, but normal numbers of dysfunctional B lymphocytes and NK cells.

5. Recombinase-Activating Gene Deficiencies

Another form of autosomal recessive SCID is due to mutations in recombinase activating genes (*RAG1* and *RAG2*), which encode proteins critical for assembling antigen receptor genes for both T and B lymphocytes. Several mutations in these genes have been described. The clinical presentation is similar to that of other forms of SCID, but the lymphocyte phenotype differs, as patients with SCID due to *RAG1* or *RAG2* mutations lack both T and B lymphocytes, but maintain normal or elevated numbers of NK cells.

**Ommen syndrome** is an autosomal recessive syndrome characterized by SCID, eczematoid rash, hepatosplenomegaly, lymphadenopathy, and alopecia. The disease is caused by mutations in *RAG1*, *RAG2*, or Artemis (see below). Laboratory evaluation reveals absent B lymphocytes, normal to elevated T-lymphocyte numbers with restricted function, and normal functional NK cells. Additionally, affected patients often have eosinophilia and elevated levels of IgE. The syndrome is typically fatal, although BMT has been used.

6. CD3-Delta-Chain Deficiency

CD3-delta-chain (CD3δ) deficiency is a rare form of autosomal recessive SCID. Homozygous defects in the CD3δ chain halt T-lymphocyte maturation. Clinical presentation and lymphocyte phenotype are similar to IL-7Rα deficiency, but CD3δ-chain deficiency differs from other forms of SCID in that these patients have a normal appearing thymic silhouette on chest radiograph.

7. CD45 Deficiency

Another rare form of autosomal recessive SCID is due to mutations in the gene for CD45. CD45 is a tyrosine phosphatase important for regulating signal transduction. Affected patients have a similar presentation to other forms of SCID and a lymphocyte phenotype with low to absent T and NK cells, but elevated B lymphocytes.

8. Artemis Deficiency

Artemis is a DNA repair factor important for repairing cuts in the double-stranded DNA essential for the assembly of antigen receptors for T and B lymphocytes. Inheritance is autosomal recessive, and clinical presentation and lymphocyte phenotype are similar to those seen in *RAG1* and *RAG2* deficiencies.
CHAPTER 31

9. ZAP-70 Deficiency

Deficiency of zeta-chain–associated protein (ZAP)-70 results in a rare form of autosomal recessive combined immunodeficiency. ZAP-70 is a tyrosine kinase critical for T-lymphocyte signaling and activation. Clinical presentation is similar to that of other forms of SCID, but most affected patients have palpable lymph nodes and visible thymic silhouette. Lymphocyte evaluation reveals absence of CD8+ T lymphocytes, normal but nonfunctional CD4+ T lymphocytes, normal numbers of poorly functioning B lymphocytes, and normal numbers and function of NK cells.

OTHER COMBINED IMMUNODEFICIENCY DISORDERS

Combined immunodeficiencies include defects that directly impair both T and B lymphocytes, as well as T-lymphocyte–specific defects, because proper B-lymphocyte function and antibody production are dependent on T-lymphocyte function. Therefore, most T-lymphocyte deficiencies manifest as combined impairments.

1. Wiskott-Aldrich Syndrome

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Immunodeficiency with recurrent infections.
- Microplatelet thrombocytopenia.
- Eczema.
- Occurs only in males.

**General Considerations**

Wiskott-Aldrich syndrome (WAS) is an X-linked recessive disease characterized by immunodeficiency, microplatelet thrombocytopenia, and eczema. The syndrome results from mutations of the gene encoding WASP at X11p. WASP is a protein involved in the rearrangement of actin and is important in interactions between T lymphocytes and antigen-presenting cells.

**Clinical Findings**

**A. Symptoms and Signs**

Common presenting symptoms include bloody diarrhea, cerebral hemorrhage, and severe infections with polysaccharide-encapsulated bacteria, but clinical presentation can vary from classic severe WAS to mild thrombocytopenia without immunodeficiency, or X-linked thrombocytopenia (XLT), depending on the mutation. Early deaths are due to bleeding and infections, but malignancies and autoimmune syndromes can develop over time. Survival beyond adolescence is rare in patients not receiving treatment, although XLT is sometimes diagnosed in adults.

**B. Laboratory Findings**

Laboratory findings that suggest the diagnosis are a low platelet count, low or absent isohemagglutinins, and reduced antibody responses to polysaccharide antigens (S pneumoniae and H influenzae). IgM may be low; IgA and IgE are often high.

**Differential Diagnosis**

In addition to WAS and XLT, the differential diagnosis in a patient with a low platelet count must include other causes of platelet consumption, destruction, and abnormal production, such as idiopathic thrombocytopenic purpura, leukemia or myelodysplasia, drug adverse effect, and infection. WAS can be differentiated from these other conditions by small-sized platelets on smear evaluation, the presence of eczema (and atopy), and documented immune dysfunction. Additionally, there is a continuum between WAS and XLT that lacks immunodeficiency. Subsequently, a scoring system has been developed to help clinicians distinguish WAS from XLT.

**Treatment**

Treatment includes infection prophylaxis with antibiotics (including trimethoprim–sulfamethoxazole for P carinii pneumonia) and IgG replacement therapy for patients with deficient antibody responses. Splenectomy to reduce thrombocytopenia has been helpful in some patients with XLT but must be followed by antibiotic prophylaxis because of the increased risk of septicemia and sudden death. Platelet transfusions should be avoided unless severe bleeding has occurred. Finally, BMT using the best-matched donor offers the possibility of a definitive cure, but is associated with morbidity and mortality.

2. 22q11.2 Deletion Syndrome (DiGeorge Syndrome)

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Congenital heart defects.
- Hypocalcemia.
- Distinctive craniofacial features.
- Thymic hypoplasia.
General Considerations

DiGeorge syndrome or 22q11.2 deletion syndrome is an autosomal dominant syndrome resulting in defective development of the third and fourth pharyngeal pouches. There is considerable variability in phenotype based on the location and extent of microdeletion. Overlapping syndromes include velocardiofacial syndrome and Shprintzen syndrome. The incidence is about 1:4000 births, and the abnormal chromosome is usually inherited from the mother. The associated immunodeficiency is secondary to the aplastic or hypoplastic thymus, where T-lymphocyte maturation occurs. Surprisingly, most patients have no or only mild immune defects. The term partial DiGeorge syndrome is commonly applied to these patients with impaired rather than absent thymus function.

Clinical Findings

A. Symptoms and Signs

Clinical characteristics include congenital heart defects, hypocalcemia due to hypoparathyroidism, distinctive craniofacial features, renal anomalies, and thymic hypoplasia. Presentation usually results from cardiac failure, or from hypocalcemia 24–48 hours postpartum. The diagnosis is sometimes made during the course of cardiac surgery when no thymus is found in the mediastinum. Additional important clinical issues include delayed speech and behavioral problems.

B. Laboratory Findings

Laboratory evaluation typically reveals normal to decreased numbers of T lymphocytes with preserved T-lymphocyte function and normal B-lymphocyte function. In the rare patient with absent or dysfunctional T lymphocytes, B-lymphocyte function and antibody production may be abnormal as well. Over time, T-lymphocyte numbers normalize in the majority of patients who have low numbers of T lymphocytes at presentation. Diagnosis is confirmed via fluorescence in situ hybridization chromosomal analysis for the microdeletion on chromosome 22.

Treatment

Treatment of the 22q11.2 deletion syndrome may require surgery for cardiac defects, and vitamin D, calcium, or parathyroid hormone replacement to correct hypocalcemia. Transfusion products should be irradiated. Both thymic grafts and BMT have been used successfully in patients with absent T-lymphocyte immunity.

3. Ataxia-Telangiectasia

Ataxia-telangiectasia (A-T) is an autosomal recessive disorder characterized by progressive cerebellar ataxia (due to degeneration of Purkinje cells), telangiectasia, and variable immunodeficiency. Ataxia develops by age 5 years, followed by the appearance of telangiectasias of the conjunctiva and exposed areas (ie, nose, ears, and shoulders). The mutated A-T protein kinase is encoded on chromosome 11 and is required for cell cycle regulation and DNA repair. The Nijmegen breakage syndrome is probably a variant of A-T with more severe clinical features, including microcephaly and birdlike facies. Abnormal findings in A-T include elevated serum α-fetoprotein levels (useful diagnostically); thymic hypoplasia and lymphopenia; immunoglobulin deficiencies, including low levels of IgA, IgE, or IgG; and defective ability to repair radiation-induced DNA fragmentation. Clinically, the most important symptom is progressive loss of motor coordination, followed by weakness. Respiratory tract infections and many types of malignancy (including carcinomas and lymphomas) are the major causes of death. There is no definitive treatment, although IVIG and aggressive antibiotics have been used with limited success. Heterozygotes may have a small increased risk for breast cancer.

4. X-Linked Hyper-IgM Syndrome

X-linked hyper-IgM or CD40 ligand deficiency is the most common form of hyper-IgM and involves a defect in CD40 ligand (CD154) on T lymphocytes. Unlike the autosomal recessive forms of hyper-IgM, the mutation results in both antibody and cell-mediated deficiencies, as the interaction between CD40L (on T cells) and CD40 (on antigen-presenting cells) is important for both antibody production and T-cell activation. Affected males have low levels of IgG and IgA, but normal or elevated levels of IgM and normal numbers of B lymphocytes. Typically, male infants present with recurrent bacterial and opportunistic infections such as P carinii pneumonia or Cryptosporidium diarrhea. Additionally, affected males have a high frequency of sclerosing cholangitis, increased liver and biliary tract carcinomas, neutropenia, and autoimmune syndromes, including thrombocytopenia, arthritis, and inflammatory bowel disease. Conservative treatment includes IVIG and antibiotic prophylaxis, but because prognosis is still quite poor, BMT has been used with preliminary success.

5. Immunodeficiency Due to Mutations of Nuclear Factor-κB-Essential Modulator

Immunodeficiency due to mutations in the gene for nuclear factor-κB—essential modulator (NEMO) is an X-linked syndrome in which male patients manifest ectodermal dysplasia (abnormal teeth, fine sparse hair, and abnormal or absent sweat glands) and defects of T- and B-lymphocytes. Many mutations are fatal in utero for male infants. Female carriers may have incontinencia pigmenti. The mutation results in abnormal immunoreceptor signaling. Surviving males present with early serious infections, including opportunistic infections such as Pneumocystis and atypical mycobacteria. Laboratory evaluation reveals hypogammaglobulinemia and poor specific antibody production, but normal numbers of T and B lymphocytes. Functional evaluation of lymphocytes demonstrates variable response. Because patients with confirmed NEMO mutations are quite rare, the best treatment course is with IVIG as well as BMT has been used. Prognosis is unknown, but aggressive antibiotic therapy in combination with IVIG as well as BMT has been used. Prognosis is dependent on the severity of immunodeficiency, with most deaths due to infection.

6. Combined Immunodeficiency with Defective Expression of Major Histocompatibility Complex Types I & II

Major histocompatibility complex class I (MHC I) deficiency or bare lymphocyte syndrome type I is an autosomal recessive combined immunodeficiency. Affected patients have abnormal TAP proteins important for intracellular transport and expression of MHC I on cell surfaces. Patients with bare lymphocyte syndrome type I present with recurrent sinopulmonary and skin infections. The diagnosis is confirmed by demonstrating an absence of MHC I expression.

Major histocompatibility complex class II (MHC II) deficiency or bare lymphocyte syndrome type II is a rare autosomal recessive combined immunodeficiency in which cells lack MHC II expression. Clinical presentation includes recurrent viral, bacterial, and fungal infections. Patients with bare lymphocyte syndrome type II have normal numbers of T and B lymphocytes, but low CD4+ lymphocyte numbers, abnormal lymphocyte function, and hypogammaglobulinemia. They also have a high incidence of sclerosing cholangitis. When this diagnosis is suspected, demonstration of absent MHC class II molecules confirms the disorder. Severe cases are fatal without BMT, but milder phenotypes may be managed with IVIG replacement and aggressive use of antibiotics.

7. Diseases Due to Defective Interferon Gamma & Interleukin-12 Pathways

The interferon-γ and IL-12 pathways are critical for macrophage, T-lymphocyte, and NK cell immunity toward mycobacterial infections. Multiple defects have been described in both the receptors for these cytokines and the receptors for signal transducer and activator of transcription molecules, with affected patients variably susceptible to atypical mycobacteria or infection after bacille Calmette-Guérin vaccination. Age of onset is variable, and symptoms can manifest in early adulthood. Treatment with supplemental interferon-γ is effective for some patients in combination with appropriate antibiotics. Most patients should also receive long-term mycobacterial prophylaxis.

8. Purine Nucleoside Phosphorylase Deficiency

Purine nucleoside phosphorylase (PNP) deficiency is an immunodeficiency due to defects in the gene encoding PNP, which is important in the purine salvage pathway. Deficiency of PNP causes toxic metabolites that result in T-lymphocyte death, but in many patients B lymphocytes are spared. This autosomal recessive disease not only results in recurrent and serious infections, but affected patients have concomitant neurologic (developmental delay, ataxia, and spasticity) and autoimmune disorders. Infections present at variable ages. Laboratory evaluation reveals low numbers of or absent T lymphocytes and a variable B-lymphocyte deficiency. Without BMT, this disease is fatal due to infection or malignancy.

PHAGOCYTIC DEFECTS

Phagocytic defects include abnormalities of both numbers (neutropenia) and function of polymorphonuclear leukocytes (neutrophils, eosinophils, and basophils). Functional defects consist of impairments in adhesion, chemotaxis, or bacterial killing.

1. Neutropenia

Evaluation for the presence of neutropenia should be included when considering recurrent infections. The diagnosis and treatment of neutropenia is discussed in Chapter 28. Additionally, some primary immunodeficiency syndromes are associated with neutropenia (eg, XLA).
2. Chronic Granulomatous Disease

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Recurrent infections with catalase-positive bacteria and fungi.
- X-linked and autosomal recessive forms.
- Caused by abnormal superoxide generation within phagocytes.

**General Considerations**

Chronic granulomatous disease is a rare immunodeficiency caused by defective superoxide generation; specifically, defects are seen in NADPH oxidase. Most cases (65%) are inherited as X-linked recessive diseases, but autosomal recessive forms also exist.

**Clinical Findings**

**A. Symptoms and Signs**

Clinical presentation is characterized by recurrent and serious infections of skin, lungs, and liver with catalase-positive bacteria, fungi, and subsequent granuloma formation. Patients also typically have lymphadenopathy, hepatosplenomegaly, and signs of chronic and recurrent skin infections.

**B. Laboratory Findings**

Patients typically present with serious infection, positive cultures, and normal numbers of white blood cells. The five most common infecting organisms are *Staphylococcus aureus*, *Burkholderia cepacia*, *Serratia marcescens*, *Nocardia* species, and *Aspergillus* species. Patients also present with granuloma development from past infections, including granulomas of the skin, liver, and genitourinary tract. Patients may have an elevated erythrocyte sedimentation rate, even between obvious infections. Diagnosis is confirmed by demonstrating lack of superoxide production via dihydrorhodamine flow cytometry. This test, unlike the nitroblue tetrazolium test, allows differentiation between X-linked and autosomal recessive forms and also demonstrates carrier status of X-linked disease.

**Differential Diagnosis**

The differential diagnosis includes other phagocytic cell abnormalities or deficiencies described in this section. Additionally, other immunodeficient states leading to recurrent bacterial or fungal infections, such as hypogammaglobulinemia, CVID, SCID, and other combined immunodeficiencies, should be considered. Notably, in contrast to these disorders, chronic granulomatous disease is defined by the absence of the superoxide burst.

**Treatment**

Treatment includes prophylactic and symptomatic use of antibiotics and antifungals in combination with interferon-γ. Additionally, BMT has been successful.

3. Leukocyte Adhesion Deficiencies Types I & II

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Recurrent serious infections.
- “Cold” abscesses without pus formation.
- Poor wound healing.
- Gingival or periodontal disease (or both).

**General Considerations**

The ability of white blood cells to travel to peripheral sites of infections is critical for effectiveness of phagocytic immunity. In leukocyte adhesion deficiency (LAD), defects in molecules required for leukocyte adherence and migration prevent these cells from arriving at the sites of infections. LAD I is an autosomal recessive disease caused by mutations in the common chain of the β2 integrin family (CD18) located on chromosome 21q22.3. These mutations result in impaired neutrophil migration in addition to poor adherence, phagocytosis, and antibody-dependent immunity.

**Clinical Findings**

**A. Symptoms and Signs**

Clinically, patients present with variable phenotypes, including recurrent serious infections, lack of pus formation, poor wound healing, and gingival and periodontal disease. The hallmark feature is little inflammation and absent neutrophils on histopathologic evaluation of infected sites (ie, “cold” abscesses) especially when concurrent with peripheral blood neutrophilia. The most severe phenotype manifests with infections in the neonatal period, including delayed separation of the umbilical cord with associated omphalitis.

**B. Laboratory Findings**

Laboratory evaluation often demonstrates a striking leukocytosis. Diagnosis of suspected cases is confirmed by flow cytometry analysis for CD18.
Treatment

Treatment includes aggressive antibiotic therapy. LAD II is a rare autosomal recessive disease caused by an inborn error in fucose metabolism that results in abnormal expression of sialyl-Lewis X (CD15s), which functions as a selectin ligand. The resulting phenotype is similar to LAD I, characterized by recurrent infections, lack of pus formation, poor wound healing, and periodontal disease, but additionally, LAD II patients have developmental delays, short stature, dysmorphic facies, and the Bombay (hh) blood group. Diagnosis is confirmed by flow cytometry analysis for CD15s, and treatment is usually limited to antibiotics, although fucose supplementation has been reported with some success.

4. Glucose-6-Phosphate Dehydrogenase Deficiency

Severe forms of X-linked glucose-6-phosphate dehydrogenase deficiency result in recurrent infections and increased risk of severe malarial infection due to abnormal neutrophil respiratory burst. Glucose-6-phosphate dehydrogenase–associated immunodeficiency is much less common than the associated hemolytic anemia.

5. Myeloperoxidase Deficiency

Leukocyte myeloperoxidase is important for intracellular destruction of Candida albicans. Although deficiency is quite common, few patients present with recurrent or chronic candidal infections. Diagnosis can be confirmed with assays measuring myeloperoxidase levels in leukocytes. Symptomatic and prophylactic antifungal therapy is often necessary in patients with recurrent infections. The myeloperoxidase gene has been localized to chromosome 17.

COMPLEMENT DEFECTS

As a component of the innate immune system, complement works through opsonization, lysis of target cells, and recruitment of phagocytic cells, and by facilitating antibody-mediated immunity. The complement system includes three pathways of enzymatic reactions: classical, alternative, and lectin (see Figure 31–4). All three pathways share C3 cleavage and result in promotion of inflammation, elimination of pathogens, and enhancement of the immune system response. Activation of the complement system occurs through bacterial proteins and surface-bound IgG and IgM antibodies.

1. Complement Factor Deficiencies

Rare deficiencies of individual complement factors (C1–C9) are inherited by autosomal recessive transmission. Deficiencies of factors C1, C2, and C4 do not predispose to increased infections, but are associated with autoimmune disorders such as systemic lupus erythematosus. Primary C3 deficiency presents with severe pyogenic infections, as C3 is critical for opsonization in both the classical and alternative pathways. There are also acquired forms of C3 deficiency that predispose patients to similar infectious risks. Terminal complement factor deficiency (C5, C6, C7, C8, and C9) or properdin (an alternative pathway factor) deficiency results in recurrent infections with Neisseria species. Survivors of meningococcal meningitis and patients with recurrent neisserial infections should be screened for such a deficiency.

Deficiency of mannose-binding lectin has been linked to increased risk of infections, but recent studies have been unable to confirm deficiency as a risk factor.

2. Hereditary Angioedema

Due to C1 Esterase Inhibitor Deficiency

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Recurrent episodes of angioedema.
► No associated urticaria or pruritus.
► Onset at any age.

General Considerations

Hereditary angioedema is a rare autosomal dominant disorder caused by C1 esterase inhibitor (C1-INH) deficiency in which susceptibility to infection is not increased. There is also an acquired form associated with angiotensin-converting enzyme inhibitor medication use or some B-lymphocyte malignancies.

Clinical Findings

A. Symptoms and Signs

Affected patients can experience edema of skin and bowel and potentially life-threatening edema of the airway. Typical sites of swelling include the face, extremities, and genitals. Trauma, accidental or intentional (eg, due to surgery, childbirth, or dental work), may induce edema. Typical problems include episodic intestinal obstruction and dental procedure-induced upper airway obstruction. The edema is usually nonpainful (unless it involves the bowel) and lasts 48–72 hours. There is no associated urticaria (ie, redness) or pruritus. Age of onset is quite variable, and there is often a positive family history.
B. Laboratory Findings

Initial screening tests for complement that show decreased CH50 or low levels of C4 suggest the diagnosis. Confirmation comes from demonstration of low or absent levels of C1-INH or poor or absent C1-INH function. Additionally, C2 and C4 levels are low, and C1q is normal.

Differential Diagnosis

Other causes of acquired angioedema, including that associated with certain medications (most notably angiotensin-converting enzyme modifying drugs), autoimmune diseases, and lymphoproliferative diseases, should be considered. Hereditary angioedema is distinguished from the acquired form of the disorder by normal levels of C1q.

Treatment

Intravenous C1-INH concentrate is the treatment of choice for the emergency management of acute edema (eg, laryngeal or diffuse facial edema, severe abdominal attacks). Volume replacement is often needed due to fluid loss from edema. Fresh-frozen plasma may be used if C1-INH concentrate is not available. Long-term prophylaxis is a consideration when attacks occur monthly or have been life-threatening. The synthetic androgen danazol prevents attacks by increasing C1-INH levels. Antifibrinolytic agents (eg, tranexamic acid) may have a preferable adverse effects profile to androgens. For short-term prophylaxis prior to dental or surgical procedures, C1-INH concentrate is preferred; tranexamic acid, danazol, or fresh-frozen plasma can also be used.

3. Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria is a rare X-linked disorder with variable disease expression in which affected patients have intravascular hemolysis, bone marrow failure, and thrombosis, but no associated immune defect. Paroxysmal nocturnal hemoglobinuria is caused by a mutation in phosphatidylinositol-glycan complementation class A, which is critical for certain erythrocyte surface proteins. Without these surface proteins, erythrocytes are highly susceptible to complement-mediated lysis. Thrombotic events, particularly intra-abdominal, are the major cause of death. Additional morbidity and mortality is due to bone marrow failure and associated bone marrow malignancies.

Other Well-Defined Immunodeficiency Syndromes

1. Hyper-IgE Syndrome

Hyper-IgE syndrome (HIES), also known as Job syndrome, is a rare primary immunodeficiency characterized by elevated levels of IgE (> 2000 IU/mL), neonatal eczematoid rash, recurrent infections with Staphylococcus aureus, recurrent pneumonia with pneumatocele formation, and typical facies. Inheritance appears to be sporadic, although autosomal dominant and recessive cases have been reported. Additional clinical findings include retained primary teeth, scoliosis, hyperextensibility, high palate, and osteoporosis. In addition to staphylococcal infections, affected patients also have increased incidence of infections due to Streptococcus spp, Pseudomonas spp, C albicans, and even opportunistic infections with Pneumocystis carinii. Laboratory evaluation reveals normal to profoundly elevated levels of IgE and occasionally an associated eosinophilia. However, elevated IgE levels themselves are not a risk factor for HIES, as atopic dermatitis and parasite infection are much more common causes of elevated IgE. Diagnosis is often difficult due to variable presentation, which may become progressively severe with increasing age. Subsequently, diagnosis is often only made over time and evolving syndrome characteristics. The underlying cause of HIES is unknown. The mainstay of treatment is prophylactic and symptomatic antibiotic use in combination with good skin care. IVIG has been used with some success to decrease infections and possibly modify IgE levels.

2. Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-Linked Syndrome

Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome is a rare disease that usually manifests with severe diarrhea and insulin-dependent diabetes mellitus within the first months of life. Affected males also have severe eczema, food allergy, autoimmune cytopenias, lymphadenopathy, splenomegaly, and recurrent infections. Most die before 2 years of age due to malnutrition or sepsis. IPEX syndrome results from mutations in the FOXP3 gene that encodes a protein essential for developing regulatory T lymphocytes. Leukocyte counts and immunoglobulin levels are generally normal. Immunosuppression and nutritional supplementation produce temporary improvements, but the prognosis is poor and most cases result in early death. BMT has been attempted with variable success.

References:

3. X-Linked Lymphoproliferative Syndrome

X-linked lymphoproliferative syndrome is an immunodeficiency that develops following EBV infection. Affected males develop fulminant infectious mononucleosis with hemophagocytic syndrome, multiple organ system failure, and bone marrow aplasia. The mutated gene encodes a signaling protein used by T lymphocytes and NK cells called SLAM adapter protein. Affected boys are immunologically normal prior to EBV infection, and during acute infection they produce antibody to EBV. In most instances, infection with EBV is fatal. Patients who survive the initial episode or who are never infected with EBV in childhood develop lymphomas, vasculitis, hypogammaglobulinemias (with elevated IgM) or common variable immunodeficiency in later life. Antenatal diagnosis is possible.

4. Chronic Mucocutaneous Candidiasis

There are two forms of chronic mucocutaneous candidiasis (CMC). The first type is an autosomal dominant disorder that is characterized by isolated candidal infections of the skin, nails, and mucous membranes, and is not due to other causes. Systemic disease is not characteristic, but case reports of intracranial mycotic aneurysms exist. Primary CMC most commonly occurs as an isolated syndrome, but can be associated with endocrine or autoimmune disorders. The underlying defect is unknown, but the prognosis is quite good with antifungal therapy.

An autosomal recessive form of CMC with associated autoimmunity, also known as autoimmune polyendocrinopathy, candidiasis, ectodermal dysplasia (APECED) syndrome, is characterized by recurrent candidal infections, abnormal T-lymphocyte response to Candida, autoimmune endocrinopathies, and ectodermal dystrophies. APECED is caused by mutations in the gene for an important transcription regulator protein called autoimmune regulator that is critical for normal thymocyte development. Treatment includes antifungal therapy in combination with therapy for associated endocrinopathies.

5. Autoimmune Lymphoproliferative Syndrome

Autoimmune lymphoproliferative syndrome (ALPS) results from mutations of genes important for regulating programmed lymphocyte death (apoptosis). Most commonly, the defect is in Fas (CD95) or Fas ligand, but other defects in the Fas pathway have also been described (eg, caspase 10). Clinical presentation includes lymphadenopathy, splenomegaly, and autoimmune disorders (autoimmune hemolytic anemia, neutropenia, thrombocytopenia, and sometimes arthritis). Occasionally, patients have frequent infections. The diagnosis is suspected when T-lymphocyte subsets by flow cytometry demonstrate elevated numbers of CD3+CD4–CD8– (double negative) T lymphocytes. Several different types of ALPS are distinguished by the response of lymphocytes to Fas-induced apoptosis. Patients are often heterozygous, and inheritance is mostly autosomal dominant. Treatment with prednisone often controls the lymphadenopathy. In some cases, BMT has been curative. Affected patients are also at risk for lymphoma. Mutations affecting another apoptosis-related protein, caspase 8, cause an ALPS variant syndrome in which the susceptibility to infection by herpes simplex virus also increases.

GENETIC SYNDROMES ASSOCIATED WITH IMMUNODEFICIENCY

Several described genetic syndromes have associated immunodeficiency that is often identified after the syndrome has been diagnosed. Usually, the immune defect is not the major presenting clinical problem.

1. Bloom Syndrome

Characteristics of Bloom syndrome include growth retardation, sun sensitivity, and telangiectasias of the face. The syndrome results from mutations in a DNA helicase that lead to excess sister chromatid exchanges. Affected patients have an increased risk of malignancy and life-threatening infections. Serum IgA and IgM are variably low, and T-lymphocyte function is abnormal.
2. Transcobalamin 2 Deficiency
Transcobalamin 2 deficiency is due to defective cellular transport of cobalamin and results in megaloblastic anemia, diarrhea, and poor growth. Affected patients have hypogammaglobulinemia and poor specific antibody production.

3. Immunodeficiency, Centromeric Instability, Facial Anomalies Syndrome
Immunodeficiency, centromeric instability, facial anomalies (ICF) syndrome is a rare condition caused by abnormal DNA methyltransferase. Unlike other chromosome instability syndromes, ICF syndrome does not have an associated hypersensitivity to sunlight. Affected patients have severe respiratory, gastrointestinal, and skin infections due to low or absent immunoglobulins and abnormal T-lymphocyte numbers and function.

4. Trisomy 21
Patients with trisomy 21 or Down syndrome have increased susceptibility to respiratory infection. Immunodeficiency is variable, and abnormal numbers and function of T and B lymphocytes have been reported. Additionally, patients have an increased incidence of autoimmune diseases.

5. Turner Syndrome
Turner syndrome (partial or complete absence of one X chromosome) is associated with increased risk of otitis media, respiratory infections, and malignancies. Immune defects are variable but may include abnormal T-lymphocyte numbers and function and hypogammaglobulinemia.

6. Chédiak-Higashi Syndrome
Chédiak-Higashi syndrome is a rare autosomal recessive disease caused by mutations in a lysosomal trafficking gene. The neutrophils of affected individuals have giant lysosomes, impaired chemotaxis, neutropenia, and abnormal NK-cell cytotoxicity. Patients present with recurrent infections (particularly periodontitis), partial oculocutaneous albinism, and neuropathy. Most patients progress to generalized lymphohistiocytic infiltration syndrome, which is a common cause of death. Treatment strategies address infections and neuropathy and the use of immunosuppression attempts to slow lymphoproliferative progression.

7. Griscelli Syndrome
Characterized by partial albinism, neutropenia, thrombocytopenia, and lymphohistiocytosis, Griscelli syndrome is a rare autosomal recessive syndrome resulting from mutations in the myosin VA gene. Affected patients have recurrent and serious infections caused by fungi, viruses, and bacteria. Immunologic evaluation demonstrates variable immunoglobulin levels and antibody function with impaired T-lymphocyte function. BMT can correct the immunodeficiency. Griscelli syndrome is distinguished from Chédiak-Higashi syndrome by the lack of granules in white blood cells.

8. Netherton Syndrome
Patients with the autosomal recessive Netherton syndrome present with trichorrhexis (brittle hair), ichthyosiform rash, and allergic diseases. A subset of patients develops recurrent infections. Immune function is variable but may include hypo- or hypergamma globulinemia, abnormal T-lymphocyte function, or abnormal phagocyte function. The disease results from mutations in a serine protease inhibitor encoded on the SPINK5 gene.

9. Cartilage-Hair Hypoplasia
Cartilage-hair hypoplasia is an autosomal recessive form of chondrodysplasia manifesting with short-limbed short stature, hypoplastic hair, defective immunity, and poor erythrogenesis. The immune defect is characterized by mild to moderate lymphopenia and abnormal lymphocyte function, but normal antibody function. Affected patients have increased susceptibility to infections and increased risk of lymphoma. The disorder results from mutation in the RMRP gene that encodes the RNA component of an RNase MRP complex. BMT can restore cell-mediated immunity but does not correct the cartilage or hair abnormalities.

Graft-versus-host disease (GVHD) occurs when immunologically competent donor T lymphocytes are grafted into a host who is unable to reject them. The immunocompetent donor T lymphocytes recognize the host as foreign, leading to significant morbidity and potentially death. In addition to BMT-associated disease, GVHD can also occur in immunodeficient patients who receive nonirradiated blood products (ie, containing liver donor T lymphocytes) or engraftment of maternally derived T lymphocytes during birth. A progressive skin rash followed by diarrhea, hepatitis, nephritis, pulmonary infiltrates, fever, and marrow damage characterize GVHD. Laboratory evaluation reveals eosinophilia and leukocytosis, and diagnosis is confirmed by biopsy. Prevention is the most successful approach to GVHD. With BMT, GVHD prophylactic immunosuppressant regimens include methotrexate, cyclosporine, and mycophenolate mofetil. Treatment of GVHD includes similar regimens in addition to antithymocyte serum, corticosteroids, and monoclonal antibodies directed against T lymphocytes.

GENERAL CONCEPTS

The classic concept that hormones are secreted substances affecting distant target cells has been updated to account for other mechanisms of hormonal action. Some hormones stimulate or inhibit metabolic processes in neighboring, not distant cells (e.g., pancreatic islets or cartilage). This mechanism is termed paracrine activity. Other hormones affect the cells that produce them, a mechanism termed autocrine. Recognition that insulin, glucagon, ghrelin, somatostatin, cholecystokinin, and other hormones are synthesized by the brain and gut supports the concept of paracrine and autocrine processes in these tissues.

Another concept of modern endocrine physiology is that specific hormone receptors in target tissues are required for hormonal action. For example, in the complete androgen insensitivity syndrome, androgen receptors are defective and affected males have varying degrees of undervirilization of the external genitalia and wolffian duct system despite having both testes (the end organ) and adequate testosterone (the hormone). Similarly, in nephrogenic diabetes insipidus or pseudohypoparathyroidism, affected children have defective antidiuretic hormone or parathyroid hormone receptor function, respectively, and have diabetes insipidus or hypoparathyroidism, despite adequate hormone secretion. Alternatively, abnormal activation of a hormone receptor leads to the effects of the hormone in the absence of excessive hormone secretion. Examples of this phenomenon are the McCune-Albright syndrome (precocious puberty and hyperthyroidism), testotoxicosis (familial male precocious puberty), and hypercalciuric hypocalcemia.

HORMONE TYPES

Hormones are of three main chemical types: peptides and proteins, steroids, and amine. The peptide hormones include those released by the anterior and posterior pituitary, pancreatic islet cells, parathyroids, lungs (angiotensin II), heart and brain (atrial and brain natriuretic hormones), and hypothalamus (releasing hormones), as well as many local growth factors (insulin-like growth factor-1). Steroid hormones are secreted primarily by the adrenal cortex, gonads, and kidney (active vitamin D [1,25(OH)₂D₃]). The amine hormones are secreted by the adrenal medulla (epinephrine) and the thyroid gland (triiodothyronine [T₃] and thyroxine [T₄]).

As a rule, the peptide hormones and epinephrine act rapidly and bind to specific receptors on the surface of their target cell. The metabolic effects of these hormones are usually stimulation or inhibition of the activity of cellular enzymes or transport proteins (post-translational effects). The steroid hormones, thyroid hormone, and active vitamin D, in contrast, act more slowly and bind to specific cytoplasmic receptors in the target cell and subsequently to specific regions (genes) on nuclear DNA, where they direct a read-out of specific protein(s). Their metabolic effects are generally stimulation or inhibition of the synthesis of enzymes or transport proteins (transcriptional effects), which increases or decreases the amount rather than the activity of these proteins in the target cell.

Metabolic processes that must be regulated rapidly such as blood glucose or calcium are usually under the control of the peptide hormones and epinephrine, whereas processes regulated more slowly such as pubertal development and metabolic rate are under the control of steroid hormones and thyroid hormone. Control of electrolyte homeostasis is intermediate and is regulated by a combination of peptide and steroid hormones (Table 32–1).

FEEDBACK CONTROL OF HORMONE SECRETION

An understanding of feedback control of hormonal secretion is fundamental to the understanding of endocrine disorders of childhood and their treatment. Hormone secretion is generally regulated by feedback in response to changes in the internal environment (see Table 32–1). When the metabolic imbalance...
is corrected, the stimulus for the hormone’s secretion ceases or is inhibited. Overcorrection of the imbalance stimulates secretion of a counterbalancing hormone or hormones.

Hypothalamic-pituitary control of hormone secretion is also regulated by feedback, so that end-organ failure (endocrine gland insufficiency) causing decreased circulating endocrine gland hormones results in increased secretion of their respective hypothalamic releasing and pituitary hormones (Table 32–1 and Figure 32–1). If restoration of normal circulating concentrations of hormones occurs, feedback inhibition at the pituitary and hypothalamus results in cessation of the previously stimulated secretion of releasing and pituitary hormones and restoration of their circulating concentrations to normal. Similarly, if there is autonomous endocrine gland hyperfunction (eg, McCune-Albright syndrome, Graves disease, or adrenal tumor), the specific hypothalamic releasing and pituitary hormones are suppressed (see Figure 32–1).

### DISTURBANCES OF GROWTH

Disturbance of growth and development is the most common problem evaluated by a pediatric endocrinologist. While most cases represent normal developmental variants, it is critical to identify abnormal growth patterns, as deviations from the norm can be the first or only manifestation of many endocrine disorders. Determination of height velocity is the most critical factor in evaluating a child’s growth. A persistent increase or decrease in height percentiles between age 2 years and the onset of puberty always warrants evaluation. It is more difficult to distinguish normal from abnormal growth in the first 2 years of life, as infants may have catch-up or catch-down growth during this period.

Appropriate standards must be used to evaluate growth. The National Center for Health Statistics provides standard growth charts for North American children (see Chapter 1). Specific growth charts are also available for some ethnic
groups. Normal values can vary by country of origin. In addition, growth charts are available for children with specific growth disturbances, such as Turner syndrome and Down syndrome.

**TARGET HEIGHT & SKELETAL MATURATION**

A child’s growth and height potential is determined largely by genetic factors. The target (midparental) height of a child is calculated from the mean parental height plus or minus 6.5 cm for boys and girls, respectively. This calculation helps identify a child’s genetic growth potential. Most children achieve an adult height within 8 cm of this number. Another parameter to determine growth potential is skeletal maturation or bone age. Beyond the neonatal period, bone age is evaluated by comparing a radiograph of the child’s left hand and wrist with the standards of Greulich and Pyle. Delayed or advanced bone age is not diagnostic of any specific disease, but the extent of skeletal maturation is used to determine remaining growth potential as a percentage of total height and allows prediction of ultimate height.

**SHORT STATURE**

Short stature has many causes. It is important to distinguish normal variants of growth (familial short stature and constitutional growth delay) and pathologic conditions (Table 32–2). Pathologic short stature is more likely in children whose growth velocity is abnormal (crossing major height percentiles on the growth curve) or who are significantly short for their family. Children with chronic illness or nutritional deficiencies may have poor linear growth, but this is typically associated with inadequate weight gain. In contrast, endocrine causes of short stature are usually associated with normal or excessive weight gain.

1. **Familial Short Stature & Constitutional Growth Delay**

Children with familial short stature typically have normal birth weight and length. In the first 2 years of life their linear growth velocity decelerates as they near their genetically determined percentile. Once this target percentile is reached, the child has normal linear growth parallel to the growth curve. Skeletal maturation and timing of puberty are consistent with chronologic age. The height percentile the child follows is maintained, and final height is short but appropriate for the family (Figure 32–2). For example, an infant boy of a mother who is 5’0” and father who is 5’5” (calculated midparental height 5’5”) may have a birth length at the 50th percentile. However, this child’s length percentile will drift downward during the first 2 years of life and will settle in at the fifth percentile where it will stay.

Children with constitutional growth delay do not necessarily have short parents but have a growth pattern similar to those with familial short stature. The difference is that children with constitutional growth delay have a delay in skeletal maturation and a delay in the onset of puberty. In these children, growth continues beyond the time the average child stops growing, and final height is appropriate for target height (Figure 32–3). There is often a history of other family members being “late bloomers.”

2. **Growth Hormone Deficiency**

Human growth hormone (GH) is produced by the anterior pituitary gland under the stimulation of growth hormone–releasing hormone (GHRH) and the inhibition of somatostatin. GH is secreted in a pulsatile pattern in response to sleep, exercise, and hypoglycemia and has direct growth-promoting and metabolic effects (Figure 32–4). GH also promotes growth indirectly by stimulating production of insulin-like growth factors, primarily IGF-1.

</tbody>
</table>

Growth hormone deficiency (GHD) is characterized by decreased growth velocity and delayed skeletal maturation in the absence of other explanations. Laboratory tests indicate subnormal GH secretion or action. GHD may be isolated or coexist with other pituitary hormone deficiencies. GHD may be congenital (septo-optic dysplasia or ectopic posterior pituitary), genetic (GH or GHRH gene mutation), or acquired (cerebropathy, germinoma, histiocytosis, or cranial irradiation). Idiopathic GHD is more common than any other cause, with an incidence of about 1:4000 children. GH resistance syndrome (Laron dwarfism) is caused by a mutation in the GH receptor. Presentation is similar to GHD, but short stature is severe and there is a distinctive facial appearance. Additional forms of GH resistance are caused by mutations in other molecular components of the GH signaling pathway.

Infants with GHD have normal birth weight with only slightly reduced length, suggesting that GH is a minor contributor to intrauterine growth. GH-deficient infants classically present as newborns with hypoglycemia or other pituitary deficiencies such as central hypothyroidism or adrenal insufficiency. Micropenis is a feature of newborn males with gonadotropin and GH deficiency. Because GH promotes lipolysis, many GH-deficient children have truncal adiposity. Growth retardation begins in infancy or may be delayed until later childhood. Regardless of onset, the primary manifestation of idiopathic or acquired GHD is subnormal growth velocity (Figure 32–3).

Laboratory tests to assess GH status may be difficult to interpret. Children with normal and short stature have a broad range of GH secretion patterns, and significant overlap exists between normal and GH-deficient children. Provocative studies are performed using such agents as insulin-induced hypoglycemia, arginine, levodopa, clonidine, or glucagon. Serum concentrations of IGF-1 and IGF-binding protein 3 may give reasonable estimations of GH secretion in the adequately nourished child (see Figure 32–4). When results of GH tests are equivocal, a trial of GH treatment can help determine whether an abnormally short child will benefit from GH. Current treatment for GHD is subcutaneous recombinant GH given 6 or 7 days per week with total weekly dose of 0.15–0.3 mg/kg.

GH therapy is approved by the U.S. Food and Drug Administration (FDA) for children with GHD and growth restriction associated with chronic renal failure, for girls with Turner syndrome, children with Prader-Willi syndrome, and children born small for gestational age (SGA) who fail to demonstrate catch-up growth by age 4. GH therapy has also been approved for children with idiopathic short stature whose current height is more than 2.25 standard deviations below the norm for age. Final height improvement may be 5–7 cm in this population. This last indication is controversial and the role of GH for idiopathic short stature is still unclear. Side effects of recombinant GH are uncommon but include benign intracranial hypertension and slipped capital femoral epiphysis. With early diagnosis and treatment, children with GHD reach normal or near-normal adult height. Recombinant IGF-1 is available for use in children with GH resistance or IGF-1 deficiency.
Figure 32-2. Typical pattern of growth in a child with familial short stature. After attaining an appropriate percentile during the first 2 years of life, the child will have normal linear growth parallel to the growth curve. Skeletal maturation and the timing of puberty are consistent with chronologic age. The height percentile the child has been following is maintained, and final height is short but appropriate for the family.
FIGURE 32–3. Typical pattern of growth in a child with constitutional growth delay. Growth slows during the first 2 years of life, similarly to children with familial short stature. Subsequently the child will have normal linear growth parallel to the growth curve. However, skeletal maturation and the onset of puberty are delayed. Growth continues beyond the time the average child has stopped growing, and final height is appropriate for target height.
3. Small for Gestational Age / Intrauterine Growth Restriction

Small-for-gestational-age (SGA) infants have birth weights below the 10th percentile for the population’s birth weight / gestational age relationship. SGA infants include constitutionally small infants growing at their potential and infants with intrauterine growth restriction (IUGR). IUGR refers to a heterogeneous group of patients who fail to grow at a normal rate in utero.

SGA/IUGR is a result of poor maternal environment, intrinsic fetal abnormalities, congenital infections, or other fetal malnutrition. Intrinsic fetal abnormalities causing SGA/IUGR (often termed primordial short stature) include Russell-Silver, Seckel, Noonan, Bloom, and Cockayne syndromes, and progeria. Many children with mild SGA/IUGR (except those with intrinsic fetal abnormalities) exhibit catch-up growth during the first 3 years. However, 15–20% remain short throughout life, particularly those whose intrauterine growth restriction occurred over several months rather than just the last 2–3 months gestation. Catch-up growth may also be inadequate in preterm SGA/IUGR infants with inadequate postnatal nutrition. Children who do not show catch-up growth may have normal growth velocity, but they will follow a lower height percentile than expected for the family. In contrast to children with constitutional growth delay, those with SGA/IUGR have skeletal maturation that corresponds to chronologic age or is only mildly delayed.

GH therapy for SGA/IUGR children with growth delay is FDA approved and appears to be effective in increasing growth velocity and final adult height.

4. Disproportionate Short Stature

Skeletal dysplasias cause disproportionate short stature. There are more than 200 types of sporadic and genetic skeletal dysplasias. Measurements of arm span and upper-to-lower body segment ratio are helpful in determining whether a child has normal body proportions. If disproportionate short stature is found, a skeletal survey may be useful because specific radiographic features characterize certain disorders. Because skeletal dysplasias are rare, the effect of GH on most types is unknown.
Figure 32–5. Typical pattern of growth in a child with acquired growth hormone deficiency. Children with acquired growth hormone deficiency have an abnormal growth velocity and fail to maintain height percentile during childhood. Other phenotypic features (central adiposity and immaturity of facies) may be present. Children with congenital growth hormone deficiency will cross percentiles during the first 2 years of life, similarly to the pattern seen in familial short stature and constitutional delay, but will fail to attain a steady height percentile subsequently.
5. Short Stature Associated with Syndromes
Short stature is associated with many syndromes, including Turner, Down, and Prader-Willi. Girls with Turner syndrome often have recognizable features such as micrognathia, webbed neck, low posterior hairline, edema of hands and feet, multiple pigmented nevi, and an increased carrying angle. In some girls, however, short stature is the only obvious manifestation. Consequently, any girl with unexplained short stature should have a chromosomal evaluation. Although girls with Turner syndrome are not usually GH-deficient, GH therapy can improve final height by an average of 6.0 cm. Duration of GH therapy is a significant predictor of long-term height gain; consequently, it is important that Turner syndrome be diagnosed early and GH started as soon as possible.

GH is also approved for growth failure in Prader-Willi syndrome. Many of these individuals are GH-deficient. GH improves growth, body composition, and physical activity in these patients. A few deaths have been reported in Prader-Willi children receiving GH. All of the deaths were in very obese children, children with respiratory impairments, sleep apnea, or unidentified respiratory infections. The role of GH, if any, in these deaths is unknown. As a precaution, it is recommended that all Prader-Willi patients be evaluated for upper airway obstruction and sleep apnea prior to starting GH therapy.

Children with Down syndrome should be evaluated for GHD only if their linear growth is abnormal compared with the Down syndrome growth chart.

6. Psychosocial Short Stature (Psychosocial Dwarfism)
Psychosocial short stature refers to growth retardation in association with emotional deprivation. Undernutrition probably contributes to growth retardation in some children. Other symptoms include bizarre eating and drinking habits, bowel and bladder incontinence, social withdrawal, and delayed speech. GH secretion in children with psychosocial short stature is diminished, but GH therapy is usually not beneficial. Foster home placement or a change in the psychological environment at home usually results in improved growth and normalization of GH secretion, personality, and eating behaviors.

Clinical Evaluation
Laboratory investigation should be guided by the history and physical examination. Data included in history and physical include size at birth, pattern of growth since birth, familial growth patterns, pubertal stage, dysmorphic features, body segment proportion, and psychological health. In a child with poor weight gain as the primary disturbance, history of chronic illness and nutritional assessment are indicated. The following laboratory tests may be useful:

1. Radiograph of left hand and wrist for bone age
2. Complete blood count (to detect chronic anemia or infection)
3. Erythrocyte sedimentation rate (often elevated in collagen-vascular disease, cancer, chronic infection, and inflammatory bowel disease)
4. Urinalysis, blood urea nitrogen, and serum creatinine (occult renal disease)
5. Serum electrolytes, calcium, and phosphorus (renal tubular disease and metabolic bone disease)
6. Stool examination for fat, serum endomysial antibody (malabsorption or celiac disease)
7. Karyotype (in girls)
8. Thyroid function tests: free thyroxine (FT4) and thyroid-stimulating hormone (TSH)
9. IGF-1 and IGF-binding protein 3

TALL STATURE
Although we usually think of growth disturbances as producing short stature, potentially serious pathologic conditions may be associated with tall stature and excessive growth (Table 32–3). Excessive GH secretion is rare and is generally associated with a functioning pituitary adenoma. GH excess leads to gigantism if the epiphyses are open and to acromegaly if the epiphyses are closed. Affected children present with an accelerated growth velocity. The diagnosis is confirmed by elevated GH and IGF-1 levels and failure of GH suppression during a standard oral glucose tolerance test.

Constitutional tall stature may be a concern to adolescent girls. However, the upper limit of acceptable height in both sexes is increasing, and concerns about excessive growth for girls are becoming less frequent. When such concerns arise, the family history, growth curve, pubertal stage, and assessment of skeletal maturation allow assessment of predicted

Central diabetes insipidus (DI) is an inability to synthesize and release vasopressin. Without vasopressin the kidneys cannot concentrate urine, causing excessive urinary water loss. Genetic causes of central DI are rare and include mutations in the vasopressin gene (mostly in the neurophysin portion of the vasopressin precursor) and the WFS1 gene that causes DI, diabetes mellitus, optic atrophy, and deafness (Wolfram or DIDMOAD syndrome). Midline brain abnormalities, such as septo-optic dysplasia and holoprosencephaly are also associated with central DI. Traumatic brain injury or neurosurgery in or near the hypothalamus or pituitary can cause transient or permanent DI. Traumatic DI often has three phases. Initially, transient DI is caused by edema in the hypothalamus or pituitary area. In 2–5 days, unregulated release of vasopressin from dying neurons causes the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Finally, permanent DI occurs if a sufficient number of vasopressin neurons are destroyed.

Tumors and infiltrative diseases of the hypothalamus and pituitary may cause DI. In children with craniopharyngioma, DI usually develops after neurosurgical intervention. In contrast, germinomas often present with DI. Germinomas may be undetectable for several years; consequently, children with unexplained DI should have regularly repeated magnetic resonance imaging (MRI). Infiltrative diseases such as histiocytosis and lymphocytic hypophysitis can cause DI. In these conditions, as in germinomas, MRI scans characteristically show thickening of the pituitary stalk. Infections involving the base of the brain also cause transient DI.

**Clinical Findings**

Onset of DI is often abrupt, characterized by polyuria, nocturia, enuresis, and intense thirst. Children with DI typically crave cold water. Hyponatremia, hyperosmolality, and dehydration occur if insufficient fluid intake due to lack of access or impaired thirst mechanism does not keep up with urinary losses. In infants, symptoms may also include failure to thrive, vomiting, constipation, and unexplained fevers. Some infants may present with severe dehydration, circulatory collapse, and seizures. Vasopressin deficiency may be masked in patients with panhypopituitarism due to the impaired excretion of free water associated with adrenal insufficiency. Treating these patients with glucocorticoids may unmask their DI.

DI is confirmed when serum hyperosmolality is associated with urine hypo-osmolarity. If the history indicates that the child can go through the night comfortably without drinking, outpatient testing is appropriate. Oral fluid intake is prohibited after midnight. Osmolality, sodium, and specific gravity of the first morning void are obtained. If urine specific gravity is greater than 1.015, DI is excluded. If urine is not concentrated, a blood sample is obtained within a few
infants with central DI. Low renal solute load and chlorothiazides may be helpful in DDAVP, to maintain normal hydration. A formula with a son, infants are treated with extra free water, rather than caloric intake could cause water intoxication. For this rea-

volume of formula or breast milk needed to ensure adequate

pressin. Due to the amount of antidiuresis, intravenous

uresis that allows uninterrupted sleep and approximately 1

low serum vasopressin concentration and an antidi-

uretic response to vasopressin administration at the end of

minutes of the urine collection for osmolality, sodium, cretinine, and calcium concentration.

If screening results are unclear or if symptoms preclude safely withholding fluids at home, a water deprivation test performed in the hospital is indicated. In this test, fluid is withheld and the child is monitored. Serum osmolality greater than 290 mOsm/kg associated with inappropriately dilute urine; osmolality less than 600 mOsm/kg is diagnostic for DI. Low serum vasopressin concentration and an antidiuretic response to vasopressin administration at the end of the test distinguishes central from nephrogenic DI. Children with central DI should have a head MRI scan with contrast to look for tumors or infiltrative processes. The posterior pituitary “bright spot” on MRI is often absent in DI.

Decreased ability to concentrate urine also occurs in hypercalcemic disorders and renal tubular abnormalities (eg, Fanconi syndrome). Primary polydipsia must be distin-

guished from DI. Children with primary polydipsia tend to have lower serum sodium levels and usually can concen-

trate their urine with overnight fluid deprivation. Some may have secondary nephrogenic DI due to dilution of the renal medullary interstitium and decreased renal concen-

trating ability, but this resolves with restriction of fluid intake.

**Treatment**

Central DI is treated with oral or intranasal desmopressin acetate (DDAVP). The aim of therapy is to provide antidiuresis that allows uninterrupted sleep and approximately 1 hour of diuresis before the next dose. Children hospitalized with acute-onset DI can be managed with intravenous vasopressin. Due to the amount of antidiuresis, intravenous fluids will need to be restricted to two-thirds the mainte-

nance rate and electrolytes closely monitored to avoid water intoxication. Infants with DI should not be treated with DDAVP. Treatment with DDAVP in association with the volume of formula or breast milk needed to ensure adequate caloric intake could cause water intoxication. For this rea-

son, infants are treated with extra free water, rather than DDAVP, to maintain normal hydration. A formula with a low renal solute load and chlorothiazides may be helpful in infants with central DI.

---

**THYROID GLAND**

**FETAL DEVELOPMENT OF THE THYROID**

The fetal thyroid synthesizes thyroid hormone as early as the 10th week of gestation. Thyroid hormone appears in fetal serum by the 11th week of gestation and increases throughout gestation. The fetal pituitary-thyroid axis functions largely independently of the maternal pituitary-thyroid axis because maternal thyroid-stimulating hormone (TSH) cannot cross the placenta. However, maternal thyroid hormone can cross the placenta in limited amounts.

A TSH surge occurs at birth, peaking at about 70 mU/L within 30–60 minutes. The surge causes thyroid hormone levels to increase rapidly in the first days of life. TSH level decreases to childhood levels within a few weeks. This physiologic neonatal TSH surge can cause a false-positive newborn screen for hypothyroidism (ie, high TSH) if the blood sample is collected on the first day of life.

**PHYSIOLOGY**

Hypothalamic thyrotropin-releasing hormone (TRH) stim-

ulates the anterior pituitary gland to release TSH. In turn, TSH stimulates the thyroid gland to take up iodine, and to synthesize and release the active hormones, thyroxine (T4) and triiodothyronine (T3). This process is regulated by negative feedback involving the hypothalamus, pituitary, and thyroid (see Figure 32–1).

T4 is the predominant thyroid hormone secreted by the thyroid gland. Most circulating T4 and T3 is bound to thyroxine-binding globulin (TBG), albumin, and prealbu-

min. Less than 1% of T3 and T4 exists as free T3 (FT3) and free T4 (FT4). T3 is deiodinated in the tissues to either T3 (active) or reverse T3 (inactive). In peripheral tissues, T3 binds to high-affinity nuclear thyroid hormone receptors in the cyto-

plasm and translocates to the nucleus, exerting its biologic effects by modifying gene expression.

The T3 level is low in hypothyroidism. It may also be low in premature infants, malnutrition, severe illness, and fol-

lowing therapy with T3. It is not clear whether premature infants with low T3 benefit from treatment. T3 is also low in situations that affect TBG. TBG levels are decreased in familial TBG deficiency, nephrosis, and in patients receiving androgens. In sepsis, TBG cleavage is increased. Treatment with certain medications (heparin, furosemide, salicylates, and phenytoin) results in abnormal binding to TBG. How-

ever, since these effects involve primarily TBG levels, and not thyroid function per se, TSH and FT4 levels remain in the normal range.

T3 and T4 levels are high in hyperthyroidism and may be elevated in conditions associated with increased TBG levels (congenital TBG excess, pregnancy, estrogen therapy) and increased thyroid hormone binding to transport proteins.

---

**Cheetham T, Baylis PH: Diabetes insipidus in children: Pathophys-

iology, diagnosis and management. Paediat Drugs 2002;4:785 [PMID: 12431131].**

HYPOTHYROIDISM (CONGENITAL & ACQUIRED HYPOTHYROIDISM)

**Essentials of Diagnosis & Typical Features**

- Growth retardation, decreased physical activity, weight gain, constipation, dry skin, cold intolerance, and delayed puberty.
- Neonates with congenital hypothyroidism often look normal but may have thick tongue, large fontanels, poor muscle tone, hoarseness, umbilical hernia, jaundice, and intellectual retardation.
- $T_4$, $FT_4$, and $T_3$ resin uptake are low; TSH levels are elevated in primary hypothyroidism.

**General Considerations**

Thyroid hormone deficiency may be congenital or acquired (Table 32–4). It can be due to defects in the thyroid gland (primary hypothyroidism) or in the hypothalamus or pituitary (central hypothyroidism).

Congenital hypothyroidism occurs in about 1:3000–1:4000 infants. Untreated, it causes severe neurocognitive impairment. Most cases are sporadic resulting from hypoplasia or aplasia of the thyroid gland or failure of the gland to migrate to its normal anatomic location (ie, lingual or sublingual thyroid gland). Another cause of congenital hypothyroidism is dyshormonogenesis due to enzymatic defects in thyroid hormone synthesis. Since antithyroid drugs, including propylthiouracil (PTU) and methimazole, freely cross the placenta, goitrous hypothyroid newborns may be born to hyperthyroid mothers treated with these drugs during pregnancy.

Low $T_4$ levels may also be caused by decreased TSH secretion associated with prolonged glucocorticoid use, dopamine, or somatostatin. Cabbage, soybeans, aminosalicylic acid, thiourea derivatives, resorcinol, phenylbutazone, cobalt, and excessive iodine intake can cause goiter and hypothyroidism during pregnancy. Many of these agents cross the placenta and should be used with caution during pregnancy. Iodine deficiency also causes hypothyroidism. In severe maternal iodine deficiency, both the fetus and the mother are $T_4$-deficient, with irreversible brain damage in the fetus.

Juvenile hypothyroidism, particularly if goiter is present, is usually a result of chronic lymphocytic (Hashimoto) thyroiditis.

Several hundred patients with resistance to thyroid hormone have been described. These syndromes are generally familial and are classified on the basis of the site of resistance (eg, generalized, pituitary, or peripheral tissue).

**Clinical Findings**

**A. Symptoms and Signs**

Even when the thyroid gland is completely absent, most newborns with congenital hypothyroidism appear normal at birth and gain weight normally for the first few months of life without treatment. Since congenital hypothyroidism must be treated as early as possible to prevent intellectual impairment, the diagnosis should be based on the newborn screening test and not on signs or symptoms. Jaundice associated with an unconjugated hyperbilirubinemia may be present in newborns with congenital hypothyroidism. Some infants may have obvious findings of thick tongue, hypotonia, large fontanels, constipation, umbilical hernia, hoarse cry, and dry skin.

Juvenile hypothyroidism often presents with short stature and abnormal weight gain. Other findings include delayed epiphyseal development, delayed closure of fontanels, and retarded dental eruption. The skin may be dry, thick, scaly, coarse, pale, cool, or mottled, or have a yellowish tinge. The

$T_3$, triiodothyronine; $T_4$, thyroxine; TRH, thyrotropin-releasing hormone.
hair may be dry, coarse, or brittle. Lateral thinning of the eyebrows may occur. Musculoskeletal findings include hypotonia and a slow relaxation component of deep tendon reflexes (best appreciated in the ankles). Muscular hypotrophy (Kocher-Debré-Semelaigne syndrome) is not commonly seen in congenital hypothyroidism. Other findings include physical and mental sluggishness, nonpitting myxedema, constipation, large tongue, hypothermia, bradycardia, hoarse voice or cry, umbilical hernia, and transient deafness. Puberty may be delayed. Metromenorrhagia may occur in older girls. Sometimes, hypothyroidism induces pseudopuberty. Galactorrhea can also occur, due to stimulation of prolactin secretion.

In hypothyroidism resulting from enzymatic defects, ingestion of goitrogens, or chronic lymphocytic thyroiditis, the thyroid gland may be enlarged. Thyroid enlargement in children is usually symmetrical, and the gland is moderately firm and not nodular. In chronic lymphocytic thyroiditis, however, the thyroid frequently has a cobblestone surface.

B. Laboratory Findings

Total T4 and FT4 levels are decreased. T3 resin uptake (T3RU) is low. In primary hypothyroidism, the serum TSH level is low or inappropriately normal. Circulating autoantibodies to thyroid peroxidase and thyroglobulin may be present. Serum prolactin may be elevated, resulting in galactorrhea. Serum GH may be decreased, with subnormal GH response to stimulation in children with severe primary hypothyroidism, as well as low IGF-1 or IGF-binding protein 3 levels, or both.

C. Imaging

Thyroid imaging, while helpful in establishing the cause of congenital hypothyroidism, is not usually obtained, as it does not affect the treatment plan. Bone age is delayed. Centers of ossification, especially of the hip, may show multiple small centers or a single stippled, porous, or fragmented center (epiphyseal dysgenesis). Cardiomegaly is common. Long-standing primary hypothyroidism may be associated with thyrotrophic hyperplasia characterized by an enlarged sella or pituitary gland.

D. Screening Programs for Neonatal Hypothyroidism

All newborns should be screened for congenital hypothyroidism shortly after birth as most do not have suggestive physical findings. Depending on the state, the newborn screen either measures the total T4 or TSH level. Abnormal newborn screening results should be confirmed immediately with a T4 and TSH level. Treatment should be started as soon as possible. Initiation of treatment in the first month of life and good compliance during infancy usually results in a normal neurocognitive outcome.

- **Differential Diagnosis**

Primary hypothyroidism due to intrinsic defects of the thyroid gland must be differentiated from central hypothyroidism due to pituitary or hypothalamic hormone deficiencies of TSH or TRH. TSH and T4 levels in combination are the most useful tests. When central hypothyroidism is diagnosed, evaluation for other pituitary hormone deficiencies and head MRI imaging are required.

- **Treatment**

Levothyroxine (75–100 mcg/m²/d) is the drug of choice for acquired hypothyroidism. In neonates with congenital hypothyroidism, the initial dose is 10–15 mcg/kg/d. Serum total T4 or FT4 concentrations are used to monitor the adequacy of initial therapy because the normally high neonatal TSH may not normalize for several days to weeks. Subsequently, T4 and TSH are used in combination, as elevations of serum TSH are sensitive early indicators of the need for increased medication or better compliance.

**THYROIDITIS**

1. **Chronic Lymphocytic Thyroiditis (Chronic Autoimmune Thyroiditis, Hashimoto Thyroiditis)**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Firm, freely movable, nontender, diffusely enlarged thyroid gland.

- Thyroid function is usually normal but may be elevated or decreased depending on the stage of the disease.
924  CHAPTER 32

General Considerations

Chronic lymphocytic thyroiditis is the most common cause of goiter and acquired hypothyroidism in childhood. It is more common in girls, and the incidence peaks during puberty. The disease is caused by an autoimmune attack on the thyroid. Susceptibility to thyroid autoimmunity (and other endocrine autoimmune disorders) is associated with certain histocompatibility alleles.

Clinical Findings

A. Symptoms and Signs

The thyroid is characteristically enlarged, firm, freely movable, nontender, and symmetrical. It may also be nodular. Onset is usually insidious. Occasionally patients note a sensation of tracheal compression or fullness, hoarseness, and dysphagia. No local signs of inflammation or systemic infection are present. Most patients are euthyroid. Some patients are symptomatically hypothyroid, and few patients are symptomatically hyperthyroid.

B. Laboratory Findings

Laboratory findings vary. Serum concentrations of TSH, T4, FT4, and T3RU are usually normal. Some patients are hypothyroid with an elevated TSH and low thyroid hormone levels. Few patients are hyperthyroid with a suppressed TSH and elevated thyroid hormone levels. Thyroid antibodies (antithyroglobulin, antithyroid peroxidase) are frequently elevated. Thyroid uptake scan adds little to the diagnosis. Surgical or needle biopsy is diagnostic but seldom indicated.

Treatment

The treatment of chronic lymphocytic thyroiditis with normal thyroid function is controversial. Full replacement doses of thyroid hormone may decrease the size of the thyroid, but may also result in hyperthyroidism. Hypothyroidism commonly develops over time. Consequently, patients require lifelong surveillance. Children with documented hypothyroidism should receive thyroid hormone replacement.

2. Acute (Suppurative) Thyroiditis

Acute thyroiditis is rare. The most common causes are group A streptococci, pneumococci, Staphylococcus aureus, and anaerobes. Oropharyngeal organisms are thought to reach the thyroid via a patent foramen cecum and thyroglossal duct remnant. Thyroid abscesses may form. The patient is always toxic with fever and chills. The thyroid gland is enlarged and exquisitely tender with associated erythema, hoarseness, and dysphagia. Thyroid function tests are typically normal. Patients have a leukocytosis, “left shift,” and elevated erythrocyte sedimentation rate. Specific antibiotic therapy should be administered.

3. Subacute (Nonsuppurative) Thyroiditis

Subacute thyroiditis (de Quervain thyroiditis) is rare. It is thought to be caused by viral infection with mumps, influenza, echovirus, coxsackievirus, Epstein-Barr virus, or adenovirus. Presenting features are similar to acute thyroiditis: fever, malaise, sore throat, dysphagia, and thyroid pain that may radiate to the ear. The thyroid is firm and enlarged. Sedimentation rate is elevated. In contrast to acute thyroiditis, the onset is generally insidious and serum thyroid hormone concentrations may be elevated.

HYPERTHYROIDISM

Essentials of Diagnosis & Typical Features

- Nervousness, emotional lability, hyperactivity, fatigue, tremor, palpitations, excessive appetite, weight loss, increased perspiration, and heat intolerance.
- Goiter, exophthalmos, tachycardia, widened pulse pressure, systolic hypertension, weakness, and smooth, moist, warm skin.
- TSH is suppressed. Thyroid hormone levels (T4, FT4, T3, T3RU) are elevated.

General Considerations

In children, most cases of hyperthyroidism are due to Graves disease, caused by antibodies directed at the TSH receptor that stimulate thyroid hormone production. Hyperthyroidism may also be due to acute, subacute, or chronic thyroiditis; autonomous functioning thyroid nodules; tumors producing TSH; McCune-Albright syndrome; exogenous thyroid hormone excess; and acute iodine exposure.

Clinical Findings

A. Symptoms and Signs

Hyperthyroidism is more common in females than males. In children, it most frequently occurs during adolescence. The course of hyperthyroidism tends to be cyclic, with spontaneous remissions and exacerbations. Symptoms include worsening school performance, poor concentration, fatigue, hyperactivity, emotional lability, nervousness, personality disturbance, insomnia, weight loss (despite increased appetite), palpitations, heat intolerance, increased perspiration, diarrhea, polyuria, and irregular menses. Signs include tachycardia, systolic hypertension, increased pulse pressure, tremor, proximal muscle weakness, and moist, warm, skin. Accelerated growth and development may occur. Thyroid storm is a rare condition characterized by fever, cardiac failure, emesis, delirium, coma, and death. Most cases of Graves disease are associated with a diffuse firm goiter. A thyroid bruit and thrill may be
present. Many cases are associated with ophthalmopals, but severe ophthalmopathy is rare.

### B. Laboratory Findings

TSH is suppressed. T₄, FT₄, T₃, FT₃, and T₃RU are elevated except in rare cases in which only the serum T₃ is elevated (T₃ thyrotoxicosis). The presence of thyroid-stimulating immunoglobulin (TSI) confirms the diagnosis of Graves disease. TSH receptor binding antibodies (TRaB) are usually elevated.

### C. Imaging

In Graves disease, radioactive iodine uptake by the thyroid is increased, whereas in subacute and chronic thyroiditis it is decreased. An autonomous hyperfunctioning nodule takes up iodine and appears as a “hot nodule” while the surrounding tissue has decreased iodine uptake. In children with hyperthyroidism, bone age may be advanced. In infants, accelerated skeletal maturation may be associated with premature fusion of the cranial sutures. Long-standing hyperthyroidism causes osteoporosis.

#### Differential Diagnosis

Hypermetabolic states (severe anemia, chronic infections, pheochromocytoma, and muscle-wasting disease) may resemble hyperthyroidism clinically but differ in thyroid function tests.

#### Treatment

### A. General Measures

In untreated hyperthyroidism, strenuous physical activity should be avoided. Bed rest may be required in severe cases.

### B. Medical Treatment

1. **β-Adrenergic blocking agents**—These agents are adjuncts to therapy. They can rapidly ameliorate symptoms such as nervousness, tremor, and palpitations, and are indicated in severe disease with tachycardia and hypertension. β₁-Specific agents such as atenolol are preferred because they are more cardioselective.

2. **Antithyroid agents (propylthiouracil [PTU] and methimazole)**—Antithyroid agents are frequently used in the initial treatment of childhood hyperthyroidism. These drugs interfere with thyroid hormone synthesis. PTU also inhibits the peripheral conversion of T₄ to T₃. It usually takes a few weeks to produce a clinical response and adequate control is usually achieved within a few months. If medical therapy is unsuccessful, more definitive therapy, such as radioablation of the thyroid or thyroidectomy, should be considered.

   **A. Initial dosage**—Methimazole is initiated at a dose of 10–60 mg/d (0.5–1 mg/kg/d) given once a day. PTU is started at a dose of 150–600 mg/d (5-10 mg/kg/d) in three divided doses. Initial dosing is continued until FT₄ or T₄ have normalized and signs and symptoms have subsided.

### B. Maintenance

The optimal dose of maintenance medication remains unclear. Recent studies suggest that 10–15 mg/d of methimazole or 100–150 mg/d of PTU provide adequate long-term control in most patients with a minimum of side effects. If the TSH level becomes elevated, many providers decrease the dose of the antithyroid agent. Some providers continue the same dose of antithyroid agent and add exogenous thyroid hormone replacement.

#### C. Toxicity

If rash, vasculitis, arthralgia or arthritis, granulocytopenia, or hepatitis occur, the drug must be discontinued.

3. **Iodide**—Large doses of iodide usually produce a rapid but short-lived blockade of thyroid hormone synthesis and release. This approach is recommended only for acute management of severely thyrotoxic patients.

### C. Radiation Therapy

Radioactive iodine ablation of the thyroid is usually reserved for children whose Graves disease is unresponsive to medications, who develop adverse effects from medications, who fail to remit after several years of medical therapy, or who are poorly adherent with therapy. Some pediatric endocrinologists advocate radioablation as first-line therapy for children with Graves disease. Antithyroid agents should be discontinued 4–7 days prior to radioablation to allow resumption of radioiodine uptake by the thyroid. ¹³¹I administered orally concentrates in the thyroid and results in gradual ablation of the gland. In the first 2 weeks following radioablation, hyperthyroidism may worsen as thyroid tissue is destroyed and thyroid hormone is released. Therapy with a β-adrenergic antagonist may be necessary for a few months until FT₄ and T₄ normalize. In most cases, hypothyroidism develops and thyroid hormone replacement is needed. Long-term follow-up studies have not shown any increased incidence of thyroid cancer, leukemia, infertility, or birth defects in patients who receive ablative doses of ¹³¹I.

### D. Surgical Treatment

Subtotal and total thyroidectomy are infrequently used in children with Graves disease. Surgery is indicated for extremely large goiters, goiters with a suspicious nodule, very young or pregnant patients, or patients refusing radioiodine ablation. Before surgery, a β-adrenergic blocking agent should be given to treat symptoms and antithyroid agents should be given for several weeks to minimize the surgical risks associated with hyperthyroidism. Iodide (eg, Lugol’s solution, 1 drop every 8 hours, or saturated solution of potassium iodide, 1–2 drops daily) should be given for 1–2 weeks prior to surgery to reduce thyroid vascularity and inhibit release of thyroid hormone. Surgical complications include hypoparathyroidism, recurrent laryngeal nerve damage, and rarely,
death. An experienced thyroid surgeon is crucial to good surgical outcome. After thyroidectomy, patients become hypothyroid and need thyroid hormone replacement.

**Course & Prognosis**

Partial remissions and exacerbations may continue for several years. Treatment with an antithyroid agent results in prolonged remissions in one third to two thirds of children.

**Neonatal Graves Disease**

Transient congenital hyperthyroidism (neonatal Graves disease) occurs in about 1% of infants born to mothers with Graves disease. It occurs when maternal TSH receptor antibodies cross the placenta and stimulate excess thyroid hormone production in the fetus and newborn. Neonatal Graves disease can be associated with irritability, IUGR, poor weight gain, flushing, jaundice, hepatosplenomegaly, and thrombocytopenia. Severe cases may result in cardiac failure and death. Hyperthyroidism may develop several days after birth, especially if the mother was treated with PTU (which crosses the placenta). Symptoms develop as PTU levels decline in the newborn after birth. Thyroid studies should be obtained at birth and repeated within the first week. Immediate management should focus on the cardiac manifestations. Temporary treatment may be necessary with iodide, antithyroid agents, β-adrenergic antagonists, or corticosteroids. Hyperthyroidism gradually resolves over 1–3 months as maternal antibodies decline. As TSH receptor antibodies may still be present in the serum of previously hyperthyroid mothers after thyroidecomy or radioablation, neonatal Graves disease should be considered in all infants of mothers with a history of hyperthyroidism.

**Thyroid Cancer**

Thyroid cancer is rare in childhood. Children usually present with a thyroid nodule or an asymptomatic asymmetrical neck mass. Dysphagia and hoarseness are unusual but may occur. Thyroid function tests are usually normal. A “cold” nodule is often seen on a technetium or radioiodine uptake scan of the thyroid. Fine-needle aspiration biopsy of the nodule assists in the diagnosis.

The most common thyroid cancer is papillary thyroid carcinoma, a well-differentiated carcinoma arising from the thyroid follicular cell. Children frequently present with local metastases to the cervical lymph nodes and occasionally with pulmonary metastasis. Despite its aggressive presentation, children with papillary thyroid carcinoma have a relatively good prognosis, with a 20-year survival rate greater than 90%. Treatment consists of total thyroidectomy and removal of all involved lymph nodes, usually followed by radioiodine ablation to destroy residual thyroid remnant and metastatic tissue left behind after surgery. Thyroid hormone replacement is then started to suppress TSH to prevent stimulation of residual thyroid tissue. Since papillary thyroid carcinoma in children is associated with a high recurrence rate, regular follow-up with serum thyroglobulin levels (a tumor marker), neck ultrasound, and radioiodine whole body scan are required.

Follicular thyroid carcinoma, medullary thyroid carcinoma, anaplastic carcinoma, and lymphoma are less common thyroid malignancies. Medullary thyroid carcinoma, due to autosomal dominant mutations in the RET proto-oncogene, arises from the thyroid C cells, which secrete calcitonin. It can occur sporadically or can be inherited in multiple endocrine neoplasia (MEN) type 2 and familial medullary thyroid carcinoma. It is associated with elevated serum calcitonin levels. In affected families, all members should be screened for the mutation, and those identified with the mutation should be treated with prophylactic thyroidecomy in early childhood.

**DISORDERS OF CALCIUM & PHOSPHORUS METABOLISM**

Serum calcium concentration is tightly regulated by the coordinated actions of the parathyroid glands, kidney, liver, and small intestine. Low serum calcium concentrations, detected by calcium-sensing receptors on the surface of parathyroid cells, stimulate parathyroid hormone (PTH) release. PTH in turn promotes release of calcium and phosphorus from bone, reabsorption of calcium from urinary...
intestinal malabsorption of calcium, chronic renal disease, rickets and may be present in rare disorders of vitamin D tetany of the newborn, and severe vitamin D deficiency hypoparathyroidism, pseudohypoparathyroidism, transient abnormally calcium binding to protein. proteins are low or in conditions such as acidosis that cause calcium, the metabolically active form, is helpful if serum calcium in the serum is protein-bound and metabolically fairly inactive. Thus, measurement of ionized serum calcium concentration rarely cause clinically relevant disease.

**HYPOCALCEMIC DISORDERS**

A normal serum calcium concentration is approximately 8.9–10.2 mg/dL, depending on the laboratory. The normal concentration of ionized calcium is approximately 1.1–1.3 mmol/L. Levels in newborns are slightly lower, and in premature infants may be as low as 7 mg/dL. Fifty to 60% of calcium in the serum is protein-bound and metabolically inactive. Thus, measurement of ionized serum calcium, the metabolically active form, is helpful if serum proteins are low or in conditions such as acidosis that cause abnormal calcium binding to protein.

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Tetany with facial and extremity numbness, tingling, cramps, spontaneous muscle contractures, carpopedal spasm, positive Trousseau and Chvostek signs, loss of consciousness, and convulsions.
- Diarrhea, prolongation of electrical systole (QT interval), and laryngospasm.
- In hypoparathyroidism or pseudohypoparathyroidism: defective nails and teeth, cataracts, and ectopic calcification in the subcutaneous tissues and basal ganglia.

**General Considerations**

Hypocalcemia is a consistent feature of conditions such as hypoparathyroidism, pseudohypoparathyroidism, transient tetany of the newborn, and severe vitamin D deficiency rickets and may be present in rare disorders of vitamin D action (receptor defects). Hypocalcemia may also occur in intestinal malabsorption of calcium, chronic renal disease, tumor lysis syndrome, or rhabdomyolysis, or as the result of an activating mutation in the calcium-sensing receptor of the parathyroid glands and kidneys (hypercalcicuric hypocalcemia). (See Table 32–5.)

Deficient PTH secretion may due to deficient parathyroid tissue (DiGeorge syndrome), autoimmunity, or sometimes, magnesium deficiency. Decreased PTH action may be due to magnesium deficiency, vitamin D deficiency, or defects in the PTH receptor (pseudohypoparathyroidism). Occasionally, PTH deficiency is idiopathic. Table 32–6 summarizes the characteristics of disorders of PTH secretion and action. Autoimmune parathyroid destruction with subsequent hypoparathyroidism may be isolated, or associated with other autoimmune disorders in the APECED syndrome (autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy, or APS-1). Hypoparathyroidism may also result from unavoidable surgical removal in patients with thyroid cancer. Other features of the DiGeorge syndrome (a deletion of 22.q11) include congenital absence of the thymus (with thymus-dependent immunologic deficiency) and cardiovascular anomalies, especially coarctation of the aorta.

Autosomal dominant hypocalcemia (also called familial hypercalcicuric hypocalcemia) is associated with a gain-of-function mutation in the calcium receptor, which causes a low serum PTH despite hypocalcemia, and excessive urinary loss of calcium. A family history of hypocalcemia may be the clue that differentiates this condition from other causes of hypocalcemia.

Transient neonatal hypoparathyroidism (transient tetany of the newborn) is caused both by a relative deficiency of PTH secretion and PTH action (see Table 32–6). The early form of this condition (first 2 weeks of life) occurs in newborns with birth asphyxia. In mothers with hyperparathyroidism, maternal hypercalcemia may suppress fetal PTH secretion and cause early transient neonatal hypoparathyroidism. Likewise, women with gestational diabetes may have relative hyperparathyroidism in the third trimester and their infants may experience transient hypoparathyroidism. Associated hypomagnesemia often aggravates the symptoms associated with hypocalcemia. The late form of neonatal hypoparathyroidism (after 2 weeks of age) occurs in infants receiving high-phosphate formulas (whole cow’s milk is a well-known example). Phosphate binds calcium and produces functional hypocalcemia.

Tumor lysis syndrome and rhabdomyolysis cause cellular destruction that liberates large amounts of intracellular phosphate that complex with serum calcium, producing functional hypocalcemia. Malabsorption states such as celiac disease impair the absorption of calcium, vitamin D and magnesium, all of which cause hypocalcemia (see Table 32–6). Hypomagnesemia, due to losses from the gastrointestinal tract or kidney, may cause or augment the severity of hypocalcemia by impairing the release of PTH.

Rickets is a term describing the characteristic clinical and bony radiologic features associated with vitamin D deficiency (see Chapter 10). Vitamin D deficiency caused by lack of sunlight exposure or dietary deficiency is the most com-

mon cause of rickets. Occult vitamin D deficiency is probably more common than is presently recognized. This concern forms the basis for the recommendation by the American Association of Pediatrics that breast-fed infants receive vitamin D supplementation of 200 IU/d. Rickets can also be caused by defects in the metabolism of vitamin D (see Table 32–5), including liver disease (impaired 25-hydroxylation), kidney disease (impaired 1-hydroxylation of 25-(OH) vitamin D), genetic deficiency of 1α-hydroxylase (vitamin D–dependent rickets), or end-organ resistance to vitamin D (vitamin D–resistant rickets).

Familial hypophosphatemic rickets has skeletal findings similar to those of vitamin D–related rickets. The defect in this condition is abnormal renal phosphate loss. Dietary deficiency of calcium may also cause rickets but more often causes osteopenia.

Clinical Findings

A. Symptoms and Signs

Prolonged hypocalcemia from any cause is associated with tetany, photophobia, blepharospasm, and diarrhea. The symptoms of tetany are numbness, muscle cramps, twitching of the extremities, carpopedal spasm, and laryngospasm. Tapping the face in front of the ear causes facial spasms (Chvostek sign). Some patients with hypocalcemia exhibit bizarre behavior, irritability, loss of consciousness, and convulsions. Retarded physical and mental development may be present. Headache, vomiting, increased intracranial pressure, and papilledema may occur. In early infancy, respiratory distress may be a presenting finding.

B. Laboratory Findings

In rickets, calcium levels may be low or normal (see Tables 32–5 and 32–6). Phosphate levels in hypocalcemia disorders may be low, normal, or high depending on the cause of the hypocalcemia. Magnesium levels may also be low. PTH levels are reduced in many hypocalcemic conditions, but may be elevated in pseudohypoparathyroidism or severe vitamin D deficiency. Measurement of urinary excretion of calcium as the calcium-to-creatinine ratio can assist in diagnosis and monitoring of therapy in children on calcitriol therapy.

C. Imaging

Soft tissue and basal ganglia calcification may occur in idiopathic hypoparathyroidism and pseudohypoparathyroidism. Various skeletal changes are associated with rickets, including cupped and irregular long bone metaphyses. Torsional deformities can result in genu varum (bowleg). Accen

tuation of the costochondral junction gives the rachitic rosary appearance seen on the chest wall.

Differential Diagnosis

Tables 32–5 and 32–6 outline the features of disorders associated with hypocalcemia. In individuals with hypoal

minemia, the total serum calcium may be low and yet the functional serum ionized calcium is normal. Ionized calcium is the test of choice for hypocalcemia in patients with low serum albumin.

Treatment

A. Acute or Severe Tetany

Hypocalcemia is corrected acutely by administration of intravenous calcium gluconate or calcium chloride; 10 mg/kg is the usual dose in acute treatment. Intravenous calcium infusions should not exceed 50 mg/min because of possible cardiac arrhythmia. Cardiac monitoring should be performed during calcium infusion.

B. Maintenance Management of Hypoparathyroidism or Chronic Hypocalcemia

The objective of treatment is to maintain the serum calcium and phosphate at near normal levels without excess urinary calcium excretion.

1. Diet—Diet should be high in calcium with added calcium supplements starting at a dose of 50–75 mg of elemental calcium per kilogram of body weight per day divided in three to four doses. The dose may be changed based on response of serum level and urinary calcium excretion. Therapy should be monitored to prevent hypercalcemia. Supplemental calcium can often be discontinued in patients with rickets after vitamin D therapy has stabilized.

2. Vitamin D supplementation—Various vitamin D preparations are available. Ergocalciferol (vitamin D₂) and calcitriol (1,25-dihydroxyvitamin D₃) are used in most cases. Ergocalciferol is preferred for treatment of vitamin D deficiency. However, impaired metabolism of vitamin D to its active end product, 1,25-(OH)₂ vitamin D, or impaired PTH function requires supplementation with calcitriol. Selection and dosage of vitamin D supplements varies with the underlying condition and the response to therapy. Monitoring of therapy is essential to avoid toxicity.

3. Monitoring—Dosages of calcium and vitamin D must be tailored for each patient. Monitoring serum calcium, urine calcium, and serum alkaline phosphatase levels at 1–3-month intervals is necessary to ensure adequate therapy and to prevent hypercalcemia and nephrocalcinosis.

The major goals of monitoring are to ensure (1) maintenance of serum calcium and phosphorus concentrations within normal ranges, (2) normalization of alkaline phosphatase activity for age, (3) regression of skeletal changes, and (4) maintenance of an age-appropriate urine calcium-to-creatinine ratio. The ratio should be less than 0.8 in newborns, 0.3–0.6 in children, and less than 0.25 in adolescents (creatinine and calcium measured in mg/dL).

Monitoring goals are somewhat different in hypophosphatemic rickets. Serum calcium and alkaline phosphatase
should be maintained within normal limits. Phosphorus levels should be corrected only to the low normal range. Monitoring of serum PTH is necessary to ensure that secondary hyperparathyroidism does not develop from excessive phosphate treatment or inadequate calcitriol replacement.

**PSEUDOHYPOPARATHYROIDISM (RESISTANCE TO PARATHYROID HORMONE ACTION)**

In pseudohypoparathyroidism (PHP), PTH production is adequate, but target organs (renal tubule, bone, or both) fail to respond because of receptor resistance. Resistance to PTH action is due to a heterozygous inactivating mutation in the stimulatory G protein subunit associated with the PTH receptor, which leads to impaired signaling. Resistance to other G protein–dependent hormones such as TSH, GHRH, and follicle-stimulating hormone (FSH)/luteinizing hormone (LH), may also be present.

There are several types of PHP with variable biochemical and phenotypic features (see Table 32–6). Biochemical abnormalities in PHP (hypocalcemia and hyperphosphatemia) are similar to those seen in hypoparathyroidism, but the PTH levels are elevated. PHP may be accompanied by a characteristic phenotype known as Albright hereditary osteodystrophy (AHO), which includes short stature; round, full facies; irregularly shortened fourth metacarpal; a short, thick-set body; delayed and defective dentition; and mild mental retardation. Corneal and lenticular opacities and ectopic calcification of the basal ganglia and subcutaneous tissues (osteoma cutis) may occur with or without abnormal serum calcium levels. Treatment is the same as for hypoparathyroidism.

Pseudopseudohypoparathyroidism (PPHP) describes individuals with the AHO phenotype, but normal calcium homeostasis. PHP and PPHP can occur in the same cohort. Genomic imprinting is probably responsible for the different phenotypic expression of disease. Heterozygous loss of the maternal allele causes PHP and heterozygous loss of the paternal allele causes PPHP.

**HYPERCALCEMIC STATES**

Hypercalcemia is defined as a serum level above 11 mg/dL. Severe hypercalcemia is a level above 13.5 mg/dL.

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Abdominal pain, polyuria, polydipsia, hypertension, nephrocalcinosis, failure to thrive, renal stones, intractable peptic ulcer, constipation, uremia, and pancreatitis.
- Bone pain or pathologic fractures, subperiosteal bone resorption, renal parenchymal calcification or stones, and osteitis fibrosa cystica.
- Impaired concentration, altered mental status, mood swings, and coma.

**General Considerations**

More than 80% of hypercalcemic children or adolescents have either hyperparathyroidism or a malignant tumor. Table 32–7 summarizes the differential diagnosis of childhood hypercalcemia.

Hyperparathyroidism is rare in childhood and may be primary or secondary. The most common cause of primary hyperparathyroidism is parathyroid adenoma. Diffuse parathyroid hyperplasia or multiple adenomas may occur in families. Familial hyperparathyroidism may be an isolated disease, or it may be associated with MEN type 1, or rarely type 2A. Hypercalcemia of malignancy is associated with

MEN, multiple endocrine neoplasia; PTH, parathyroid hormone.
solid and hematologic malignancies and is due either to local destruction of bone by tumor or to ectopic secretion of PTH-related protein. When ectopic PTH-related protein is present, calcium is elevated, serum PTH is suppressed, and serum PTH-related protein is elevated. Chronic renal disease with impaired phosphate excretion is the most common secondary cause of hyperparathyroidism.

Clinical Findings

A. Symptoms and Signs

1. Due to hypercalcemia—Manifestations include hypotonicity and muscle weakness; apathy, mood swings, and bizarre behavior; nausea, vomiting, abdominal pain, constipation, and weight loss; hyperextensibility of joints; and hypertension, cardiac irregularities, bradycardia, and shortening of the QT interval. Coma occurs rarely. Calcium deposits occur in the cornea or conjunctiva (band keratopathy) and are detected by slitlamp examination. Intractable peptic ulcer and pancreatitis occur in adults but rarely in children.

2. Due to increased calcium and phosphate excretion—Loss of renal concentrating ability causes polyuria, polydipsia, and calcium phosphate deposition in renal parenchyma or as urinary calculi with progressive renal damage.

3. Due to changes in the skeleton—Initial findings include bone pain, osteitis fibrosa cystica, subperiosteal bone absorption in the distal clavicles and phalanges, absence of lamina dura around the teeth, spontaneous fractures, and moth-eaten appearance of the skull on radiographs. Later, there is generalized demineralization with high risk of subperiosteal cortical bone.

B. Imaging

Bone changes may be subtle in children. Technetium sestamibi scintigraphy is preferred over conventional procedures (ultrasound, computed tomography [CT], and MRI) for localizing parathyroid tumors.

Treatment

A. Symptomatic Management

Initial management is vigorous hydration with normal saline and forced calcium diuresis with a loop diuretic such as furosemide (1 mg/kg given every 6 hours). If response is inadequate, glucocorticoids or calcitonin may be used. Bisphosphonates, standard agents for the management of acute hypercalcemia in adults, are being used more often in refractory pediatric hypercalcemia.

B. Chronic Hypercalcemia

Treatment options vary with the underlying cause. Resection of parathyroid adenoma or subtotal removal of hyperplastic parathyroid glands is the preferred treatment. Postoperatively, hypocalemia due to the rapid remineralization of chronically calcium-deprived bones may occur. A diet high in calcium and vitamin D is recommended immediately postoperatively and is continued until serum calcium concentrations are normal and stable. Treatment of secondary hyperparathyroidism from chronic renal disease is primarily directed at controlling serum phosphorus levels with phosphate binders. Pharmacologic doses of calcitriol are used to suppress PTH secretion. Long-term therapy for hypercalcemia of malignancy is the treatment of the underlying disorder.

Course & Prognosis

The prognosis after resection of a single adenoma is excellent. The prognosis following subtotal parathyroidectomy for diffuse hyperplasia or removal of multiple adenomas is usually good and depends on correction of the underlying defect. In patients with multiple sites of parathyroid adenoma or hyperplasia, MEN is likely, and other family members may be at risk. Genetic counseling and DNA analysis to determine the specific gene defect are indicated.

FAMILIAL HYPOCALCIURIC HYPERCALCEMIA

(FAMILIAL BENIGN HYPERCALCEMIA)

Familial hypocalciuric hypercalcemia is distinguished by low to normal urinary calcium excretion as a result of high renal reabsorption of calcium. PTH is normal or slightly elevated. In most cases, the genetic defect is a mutation in the membrane-bound calcium-sensing receptor expressed on parathyroid and renal tubule cells. It is inherited as an autosomal dominant trait with high penetrance. There is a low rate of new mutations. Most patients are asymptomatic, and treatment is unnecessary. A severe form of symptomatic neonatal hyperparathyroidism may occur in infants homozygous for the receptor mutation.

HYPERVITAMINOSIS D

Vitamin D intoxication is almost always the result of ingestion of excessive amounts of vitamin D. Signs, symptoms, and treatment of vitamin D–induced hypercalcemia are the same as those in other hypercalcemic conditions. Treatment depends on the stage of hypercalcemia. Severe hypercalcemia requires hospitalization and aggressive intervention. Due to the storage of vitamin D in the adipose tissue, several months of a low-calcium, low–vitamin D diet may be required.

IDIOPATHIC HYPERCALCEMIA OF INFANCY (WILLIAMS SYNDROME)

Williams syndrome is an uncommon disorder of infancy characterized by elfin-appearing facies and hypercalcemia in infancy. Other features include failure to thrive, mental and motor retardation, cardiovascular abnormalities (primarily
supravalvular aortic stenosis), irritability, purposeless movements, constipation, hypotonia, polyuria, polydipsia, and hypertension. A gregarious and affectionate personality is the rule in children with the syndrome. Hypercalcemia may not appear until several months after birth. Treatment consists of restriction of dietary calcium and vitamin D (Cacilo formula) and, in severe cases, moderate doses of glucocorticoids.

A defect in the metabolism of, or responsiveness to, vitamin D is postulated as the cause of Williams syndrome. Elastin deletions localized to chromosome 7 have been identified in more than 90% of patients. Fluorescent in-situ hybridization analysis (FISH) may be the best initial diagnostic tool. The risk of hypercalcemia generally resolves by age 4 years and dietary restrictions can be relaxed.

**IMMOBILIZATION HYPERCALCEMIA**

Abrupt immobilization, particularly in a rapidly growing adolescent, may cause hypercalcemia and hypercalciuria. Abnormalities often appear 1–3 weeks after immobilization. Medical or dietary intervention may be required in severe cases.

**HYPOPHOSPHATASIA**

Hypophosphatasia is a rare autosomal recessive condition characterized by deficiency of alkaline phosphatase activity in serum, bone, and tissues. Enzyme deficiency leads to poor skeletal mineralization with clinical and radiographic features similar to rickets. Six different clinical forms are identified. The perinatal form is characterized by severe skeletal deformity and death within a few days of birth. The infantile form includes failure to thrive, hypotonia, and craniosynostosis. The childhood form manifests with variable skeletal findings, reduced bone mineral density, and premature loss of deciduous teeth. Serum calcium levels may be elevated. The diagnosis of hypophosphatasia is made by demonstrating elevated urinary phosphoethanolamine associated with low serum alkaline phosphatase. Therapy is generally supportive. Children who survive the neonatal period may experience gradual improvement. Calcitriol may be of value for the acute treatment of hypercalcemia.

**AMBIGUOUS GENITALIA**

Ambiguous genitalia is the result of incomplete or disordered genital or gonadal development that causes a discordance between genetic sex, gonadal sex, and phenotypic sex. When an infant is born with ambiguity, immediate consultation with pediatric endocrinology, urology, and if possible psychiatry is required. Disorders of sexual differentiation stem from alterations in three main processes: gonadal differentiation, steroidogenesis, or androgen action.

1. **Disorders of Gonadal Differentiation**

These abnormalities include XY sex reversal, XX sex reversal, XY gonadal dysgenesis, true hermaphroditism, vanishing testes, and Leydig cell hypoplasia. Patients with XY sex reversal usually have pure gonadal dysgenesis. They have completely normal female external genitalia and present as girls with delayed puberty and amenorrhea. XX sex reversal, characterized by masculine or ambiguous genital development in an XX individual, can be caused by translocation of the SRY gene to the X chromosome. A true hermaphrodite must have both ovarian and testicular tissue and typically has a karyotype of 46,XX. Individuals with XY gonadal dysgenesis usually have a mosaic karyotype in which some cell lines are 45,XO and others are 46,XY. These individuals may present with normal male phenotype or ambiguity. Dyssgenetic gonads have an increased risk for neoplastic transformation. Because of decreased testosterone production in utero, 46,XY individuals with vanishing testes or Leydig cell hypoplasia will have some degree of undervirilization.

2. **Disorders of Steroidogenesis**

These disorders generally present as micropenis, genital ambiguity, or complete absence of male external genitalia in an XY individual (Figure 32–6). Testicular tissue is present and produces antimüllerian hormone. Thus, internal struc-
Disorders in this category include enzymatic defects in testosterone synthesis (12-ketoreductase deficiency) or defects in conversion of testosterone to DHT ($5\alpha$-reductase deficiency). If the enzyme defect is incomplete, the external genitalia may masculinize at puberty when testosterone production increases. Since the gonads and adrenal gland share common enzymes of steroid hormone production, some of the enzymatic defects associated with male genital ambiguity may also affect production of cortisol and aldosterone, leading to cortisol deficiency and salt wasting (see later section on the Adrenal Cortex). In an XX individual, the most common disorder in this category is congenital adrenal hyperplasia secondary to 21-hydroxylase deficiency. In the classic salt-losing form of this disorder, infant girls present with genital ambiguity but have normal uterus and ovaries.

### 3. Disorders of Androgen Action

Defects in testosterone action result from absent or defective androgen receptors (androgen insensitivity). Depending on the degree of abnormality in androgen binding, the genital phenotype can range from relatively mild male ambiguity to complete female external development.

### 4. Miscellaneous Syndromes

Syndromes such as VATER (vertebral defects, anal atresia, tracheoesophageal fistula with esophageal atresia, and radial and renal anomalies), WAGR (Wilms tumor, aniridia, genitourinary malformations, and mental retardation), Denys-Drash, and Smith-Lemli-Opitz produce a wide variety of congenital anomalies, including genital ambiguity. Maternal exposure to androgens or androgen antagonists is a rare cause of genital ambiguity in newborns.

### ABNORMALITIES IN FEMALE PUBERTAL DEVELOPMENT & OVARIAN FUNCTION

#### 1. Precocious Puberty in Girls

Precocious puberty is defined as pubertal development occurring below the age limit set for normal onset of puberty. Puberty is considered precocious in girls if the onset of secondary sexual characteristics occurs before age 8 years. Precocious puberty is more common in girls than in boys. This disparity is explained by the large number of girls with central idiopathic precocity, a rare condition in boys. Girls between 6 and 8 years of age may also show signs of puberty but it can be a benign, slowly progressing form that requires no intervention. The age of pubertal onset may be advanced by obesity.
Central (gonadotropin-releasing hormone [GnRH]-dependent) precocious puberty involves activation of the hypothalamic GnRH pulse generator, an increase in gonadotropin secretion, and a resultant increase in production of sex steroids (Table 32–9). The sequence of hormonal and physical events in central precocious puberty is identical to that of normal puberty. Central precocious puberty in girls is generally idiopathic but may be secondary to central nervous system (CNS) abnormality that disrupts the prepubertal restraint on the GnRH pulse generator. Such CNS abnormalities include, but are not limited to, hypothalamic hamartomas, CNS tumors, cranial irradiation, hydrocephalus, and trauma. Peripheral precocious puberty (GnRH-independent) occurs independent of gonadotropin secretion. In girls, peripheral precocious puberty is caused by ovarian or adrenal tumors, ovarian cysts, congenital adrenal hyperplasia, McCune-Albright syndrome, or exogenous estrogen. Estrogen-secreting ovarian or adrenal tumors are rare. Girls with these tumors typically present with markedly elevated estrogen levels and rapidly progressive pubertal changes.

</table>

GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin.
McCune-Albright syndrome is a triad of irregular café-au-lait lesions, polyostotic fibrous dysplasia, and GnRH-independent precocious puberty. It is caused by an activating mutation in the gene encoding the α-subunit of Gs, the G protein that stimulates adenyl cyclase. Endocrine cells with this mutation have autonomous hyperfunction and secrete excess amounts of their respective hormones.

Clinical Findings

A. Symptoms and Signs

Female central precocious puberty usually starts with breast development, followed by pubic hair growth and menarche. The order may vary. Girls with ovarian cysts or tumors generally have signs of estrogen excess such as breast development and possibly vaginal bleeding. Adrenal tumors or congenital adrenal hyperplasia produce signs of adrenarche (ie, pubic hair, axillary hair, acne, and sometimes, increased body odor). Children with precocious puberty usually have accelerated growth and may temporarily be tall for age. However, because skeletal maturation advances at a more rapid rate than linear growth, final adult stature may be compromised.

B. Laboratory Findings

One of the first steps in evaluating a child with early pubertal development is obtaining a radiograph of the left hand and wrist to determine skeletal maturity (bone age). If the bone age is advanced, further evaluation is warranted. In central precocious puberty, the basal serum concentrations of FSH and LH may still be in the prepubertal range. Thus, documentation of the maturity of the hypothalamic-pituitary axis depends on demonstrating a pubertal LH response after stimulation with a GnRH agonist. In peripheral precocious puberty, basal serum FSH and LH are low, and the LH response to GnRH stimulation is suppressed by feedback inhibition of the hypothalamic-pituitary axis by the autonomously secreted gonadal steroids (see Figure 32–1). In girls with an ovarian cyst or tumor, estradiol levels will be markedly elevated. In girls with signs of adrenarche and an advanced bone age, androgen levels (testosterone, androstenedione, dehydroepiandrosterone) and possible adrenal intermediate metabolites (such as 17-hydroxyprogesterone) should be measured.

C. Imaging

When a diagnosis of central precocious puberty is made, an MRI of the brain should be done to evaluate for CNS lesions. It is unlikely that an abnormality will be found in girls 6–8 years of age, so the need for an MRI in this age group should be individually assessed. In girls whose laboratory tests suggest peripheral precocious puberty, an ultrasound of the ovaries and adrenal gland is indicated.

Treatment

Girls with central precocious puberty can be treated with GnRH analogues, such as leuprolide. GnRH analogues downregulate pituitary GnRH receptors and thus decrease gonadotropin secretion. With treatment, physical changes of puberty regress or cease to progress, and linear growth slows to a prepubertal rate. Projected final heights often increase as a result of slowing of skeletal maturation. Usually, GnRH analogues are given as a monthly depot intramuscular injection and side effects are rare. After stopping therapy, pubertal progression resumes, and ovulation and pregnancy have been documented. Therapy is instituted for both psychosocial and final height considerations.

Treatment of peripheral precocious puberty is dependent on the underlying cause. In a girl with an ovarian cyst, intervention is generally not necessary, as the cyst usually regresses spontaneously. Treatment with glucocorticoids is indicated for congenital adrenal hyperplasia. Surgical resection is indicated for the rare adrenal or ovarian tumor.

In McCune-Albright syndrome, therapy with antiestrogens (eg, tamoxifen), agents that block estrogen synthesis (ketoconazole), or aromatase inhibitors (eg, letrozole) may be effective. Regardless of the cause of precocious puberty or the medical therapy selected, attention to the psychological needs of the patient and family is essential.

2. Benign Variants of Precocious Puberty

Premature thelarche (benign early breast development) occurs most commonly at 12–36 months. It is often bilateral but may begin or remain unilateral. In the absence of other signs of pubertal development (accelerated growth rate or skeletal maturation, pubic hair, vaginal mucosal maturation), no laboratory evaluation is necessary. Treatment is parental reassurance regarding the self-limited nature of the condition. Observation of the child every few months is also indicated. Onset of thelarche after age 36 months or in association with other signs of puberty requires evaluation.

Premature adrenarche (benign early adrenal maturation) is manifested by development of pubic hair and body odor, and less commonly, axillary hair and can occur before age 8 years. No increase in growth rate or skeletal maturation occurs, and no abnormal virilization (eg, clitoromegaly) is present. No treatment is required, although girls with premature adrenarche are at risk for developing polycystic ovarian syndrome during puberty.

3. Delayed Puberty

Delayed puberty in girls should be evaluated if there are no pubertal signs by age 13 years or menarche by 16 years. Failure to complete pubertal development to Tanner stage V within 4 years of onset is considered delay. Primary amenorrhea refers to the absence of menarche, and secondary amenorrhea refers to the cessation of established menses for at least 6 months.

The most common cause of delayed puberty is constitutional growth delay (Table 32–10). This growth pattern, characterized by short stature, normal growth velocity, and a delay in skeletal maturation, is described in detail earlier in this chapter. The timing of puberty is related to the bone age, not the chronologic age. Girls may also have delayed puberty from any condition that delays growth and skeletal maturation, such as hypothyroidism and growth hormone deficiency.

Primary hypogonadism in girls refers to a primary abnormality of the ovaries. The most common diagnosis in this category is Turner syndrome, in which the lack of or an abnormal second X chromosome leads to early loss of oocytes and accelerated stromal fibrosis. Other types of primary ovarian insufficiency are less common, including 46,XY gonadal dysgenesis, 46,XX gonadal dysgenesis, galactosemia, and autoimmune ovarian failure. Radiation and chemotherapy can also cause primary ovarian insufficiency.

Central hypogonadism refers to a hypothalamic or pituitary deficiency of GnRH or FSH/LH, respectively. Central hypogonadism can be functional (reversible), or caused by stress, undernutrition, prolactinemia, excessive exercise, or chronic illness. Permanent central hypogonadism is typically associated with conditions that cause multiple pituitary hormone deficiencies, such as congenital hypopituitarism, CNS tumors, or cranial irradiation. Isolated gonadotropin deficiency is rare but may occur in Kallmann syndrome, which is also characterized by hyposmia or anosmia. In either primary or central hypogonadism, signs of adrenarche are generally present.

Delayed menarche or secondary amenorrhea may result from primary ovarian failure or central hypogonadism, or may be the consequence of hyperandrogenism, anatomic obstruction precluding menstrual outflow, or müllerian agenesis. This latter disorder is called Mayer-Rokitansky-Küster-Hauser syndrome and is characterized by an absent vagina and various uterine abnormalities, with or without renal and skeletal anomalies.

Girls with complete androgen insensitivity syndrome (androgen receptor defect) typically present with primary amenorrhea, breast development, and absence of sexual hair. The affected individual (46,XY) has functioning testes that produce müllerian-inhibiting hormone during fetal life. Thus no müllerian duct (oviduct or uterus) development occurs. External genitalia are female because of the lack of androgen action. At puberty, testosterone produced in the testes is aromatized to estrogen resulting in breast development.

Clinical Evaluation

The history should ascertain whether and when puberty commenced, level of exercise, nutritional intake, stressors, sense of smell, symptoms of chronic illness, and family history of delayed puberty. Past growth records should be assessed to determine if height and weight velocity have been appropriate. Physical examination includes body proportions, breast and genital development, and stigmata of Turner syndrome. Pelvic examination or pelvic ultrasonography should be considered, especially in girls with primary amenorrhea.

A bone age radiograph should be obtained first. If the bone age is lower than that consistent with pubertal onset (< 12 years in girls), evaluations should focus on finding the cause of the bone age delay. If short stature and normal growth velocity are present, constitutional growth delay is likely. If growth rate is abnormal, laboratory studies may include a complete blood count, erythrocyte sedimentation rate, chemistry panel, and renal and liver function tests to look for unsuspected chronic medical illness. Evaluation for hypothyroidism and growth hormone deficiency may also be indicated. Measurement of FSH and LH may not be helpful in the setting of delayed bone age since prepubertal levels are normally low. Determination of a karyotype should be considered if there is short stature, or any stigmata of Turner syndrome.

If the patient has attained a bone age of more than 12 years consistent with onset of puberty and there are minimal or no signs of puberty on physical examination, FSH and LH levels will distinguish between primary ovarian failure and central hypogonadism. Primary ovarian failure is also called hypergonadotropic hypogonadism, as there is lack of estrogen feedback to the brain with elevated FSH and LH. If gonadotropins are elevated, a karyotype is the next step, as

---

</tbody>
</table>
Turner syndrome is the most common cause of female hypogonadotropic hypogonadism. Central hypogonadism is characterized by low gonadotropin levels, and evaluation is geared toward determining if the hypogonadism is functional or permanent. Laboratory tests should be directed toward identifying chronic disease and hyperprolactinemia. Cranial MRI may be helpful.

In girls with adequate breast development and amenorrhea, a progesterone challenge may be helpful to determine if sufficient estrogen is being produced. Girls who are producing estrogen have a withdrawal bleed after 5–10 days of oral progesterone, whereas those who are estrogen-deficient have little or no bleeding. The exception is girls with an absent uterus (androgen insensitivity or Mayer-Rokitansky-Küster-Hauser syndrome). They have sufficient estrogen but cannot have withdrawal bleeding. The most common cause of amenorrhea in girls with sufficient estrogen is polycystic ovarian syndrome. Girls who are estrogen-deficient should be evaluated similarly to those who have delayed puberty.

### Treatment

Replacement therapy in hypogonadal girls begins with estrogen alone at the lowest available dosage. Oral preparations such as estradiol or topical patches are used. Cyclic estrogen–progesterone therapy is started 12–18 months later, and eventually the patient may be switched over to a birth control pill for convenience. Progesterone therapy is needed to counteract the effects of estrogen on the uterus, as unopposed estrogen promotes endometrial hyperplasia. Estrogen is also necessary to promote bone mineralization and prevent osteoporosis.

### 4. Secondary Amenorrhea

See discussion of amenorrhea in Chapter 3.

### ABNORMALITIES IN MALE PUBERTAL DEVELOPMENT & TESTICULAR FUNCTION

#### 1. Precocious Puberty in Boys

Puberty is considered precocious in boys if secondary sexual characteristics appear before age 9 years. While the frequency of central precocious puberty is much lower in boys than girls, boys are more likely to have an associated CNS abnormality (see Table 32–9).

Several types of gonadotropin-independent (peripheral) precocious puberty occur in boys (see Table 32–9). Increased adrenal androgen production from an adrenal tumor or from a virilizing form of congenital adrenal hyperplasia (CAH) will cause pubertal changes in boys. Familial male-limited gonadotropin-independent puberty (testotoxicosis) is a condition in which a mutated LH receptor on the Leydig cell is autonomously activated, resulting in testicular production of testosterone despite prepubertal LH levels. McCune-Albright syndrome can also occur in boys. Leydig cell tumors of the testis cause rapid onset of unilateral testicular enlargement and physical signs of testosterone excess. Human chorionic gonadotropin (HCG)–secreting tumors such as teratomas, CNS germinomas, and hepatoblastomas also cause early puberty in boys as HCG can stimulate the Leydig cells to produce testosterone.

#### Clinical Findings

**A. Symptoms and Signs**

In precocious development, increased growth rate and growth of pubic hair are the most common presenting signs. Testicular size may differentiate central precocity, in which the testes enlarge, from gonadotropin-independent causes in which the testes usually remain small (< 2 cm in the longitudinal axis). Tumors of the testes are associated with either asymmetrical or unilateral testicular enlargement.

**B. Laboratory Findings**

Elevated testosterone levels verify early pubertal status but do not differentiate the source. As in girls, basal serum LH and FSH concentrations may not be in the pubertal range in boys with central precocious puberty, but the LH response to GnRH stimulation testing is pubertal. Sexual precocity caused by CAH is usually associated with abnormal plasma dehydroepiandrosterone, androstenedione, 17-hydroxyprogesterone (in CAH due to 21-hydroxylase deficiency), 11-deoxycortisol (in CAH due to 11-hydroxylase deficiency), or a combination of these steroids (see later section on the Adrenal Cortex). Serum β–HCG concentrations can signify the presence of an HCG-producing tumor (eg, CNS dysgerminoma or hepatoma) in boys who present with apparent true isosexual precocity (ie, accompanied by testicular enlargement) but suppressed gonadotropins following GnRH testing.

**C. Imaging**

In all boys with central precocious puberty, cranial MRI should be obtained to evaluate for a CNS abnormality. Ultrasonography may be useful in detecting hepatic, adrenal, and testicular tumors.

#### Treatment

Treatment of central precocious puberty in boys is similar to that in girls. Treatment of McCune-Albright syndrome or familial Leydig cell hyperplasia with agents that block steroid synthesis (ketoconazole), with antiandrogens (spironolac-
Klinefelter syndrome; however, the usual presentation of this most common cause of primary hypogonadism in boys is to indicate primary hypogonadism or testicular failure. The cause is likely a diagnosis. Elevated gonadotropin levels velocity is normal, constitutional growth delay is the most likely diagnosis.

Clinical Evaluation

The history should focus on whether and when puberty has started, testicular descent, symptoms of chronic illness, nutritional intake, sense of smell, and family history of delayed puberty. Physical examination should include body proportions, height and weight, pubertal stage, and testicular location, size, and consistency. Testes less than 2 cm in length are prepubertal; testes more than 2.5 cm in length suggest early pubertal growth.

A radiograph of the left hand and wrist to assess bone age should be the first step in evaluating a boy with delayed puberty. If bone age is delayed (<11–12 years) and growth velocity is normal, constitutional growth delay is the most likely diagnosis.

Laboratory evaluation includes LH and FSH levels (especially if bone age is >12 years). Elevated gonadotropin levels indicate primary hypogonadism or testicular failure. The most common cause of primary hypogonadism in boys is Klinefelter syndrome; however, the usual presentation of this disorder is not delayed puberty but failure to complete puberty with a discrepancy noted between testicular size (small) and degree of virilization. If gonadotropin values are low, the working diagnosis is central hypogonadism and further evaluation should focus on looking for pituitary hormone deficiencies, chronic disease or undernutrition (or both), hyperprolactinemia, and CNS abnormalities.

Treatment

Boys with simple constitutional delay may be offered a short (4–6 months) course of low-dose depot testosterone (50–75 mg per month) to stimulate their pubertal appearance and “jump-start” their endogenous development. In adolescents with permanent hypogonadism, treatment with depot testosterone, beginning with 50–75 mg intramuscularly each month, may be used until growth is complete. Thereafter, adult dosing (150–200 mg every 2–3 weeks) may be used. An alternative to intramuscular injections is testosterone gel, either in single-dose packets or in a pump set to dispense a preset dose. Gel is applied daily after showering. Specific therapy for GnRH deficiency with pulsatile subcutaneous GnRH may promote fertility in patients with hypothalamic-pituitary insufficiency. However, the inconvenience of treatment and the need for repeated doses for long periods of time have limited its application in pediatrics.

Cryptorchidism

Cryptorchidism (undescended testis) is common. It is most often unilateral and right-sided. At birth, approximately 4% of full-term male newborns have an undescended testis, with a higher proportion among premature infants (9–30%). In over 50% of these patients, the cryptorchid testis descends by the third month. By age 1 year, the prevalence of cryptorchidism is about 1%. Further descent may occur through puberty, perhaps stimulated by endogenous gonadotropins.

Infertility and testicular malignancy are major risks of cryptorchidism. The exact incidence of impaired fertility is unknown and incidence figures vary. However, histologic changes clearly occur as early as age 6 months in children with undescended testes. The reported malignancy rate in men with a cryptorchid testis is 48.9 per 100,000, 22 times the rate in the general population. In addition, tumors may develop in the contralateral testis, indicating that abnormal testicular development (dysgenesis) may be bilateral in unilateral cryptorchidism. In most cases, true cryptorchidism is thought to be the result of testicular dysgenesis. Cryptorchid testes frequently have a short spermatic artery and or poor blood supply. Although early scrotal positioning of undescended testes (orchidopexy) obviates further damage related to the intra-abdominal location, the testes generally remain abnormal, spermatogenesis is rare, and the risk of malignant neoplasm is increased.

Cryptorchidism can occur in an isolated fashion or associated with other findings. Abnormalities in the hypothe-
lamic-pituitary-gonadal axis predispose to cryptorchidism. Androgen biosynthesis or receptor defects also predispose to cryptorchidism and undervirilization.

The diagnosis of bilateral cryptorchidism in an apparently normal male newborn should never be made until the possibility that the child is actually a fully virilized female with potentially fatal salt-losing CAH has been considered.

▶ Clinical Findings

In infants younger than 3–4 months of age, LH, FSH, and testosterone levels help determine whether testes are present. After this time, an HCG stimulation test is done to confirm the presence or absence of abdominal testes. Ultrasonography, CT scanning, and MRI may detect testes in the inguinal region, but these studies are not completely reliable in finding abdominal testes.

▶ Differential Diagnosis

In palpating the testis, the cremasteric reflex that causes the testis to retract into the inguinal canal or abdomen (pseudocryptorchidism) may be elicited. To prevent retraction during examination, the fingers first should be placed across the abdominal ring and the upper portion of the inguinal canal to obstruct testicular ascent. Examination while the child is in the squatting position or in a warm bath is helpful. No treatment for retractile testes is necessary, and the prognosis for testicular descent and function is excellent.

▶ Treatment

A. Surgical Treatment

The current recommendation for treatment of cryptorchidism is that surgical orchidopexy be performed by an experienced surgeon if descent has not occurred by 1 year of age.

B. Hormonal Treatment

HCG at doses ranging from 250–1000 IU twice weekly for 5 weeks has been used for treatment. Such therapy generally causes descent of retractile testes, but is rarely successful in treating cryptorchidism. Androgen treatment (depot testosterone) is indicated as replacement therapy in the male child who lacks functional testes beyond the normal age of puberty.

4. Gynecomastia

Gynecomastia is a common, self-limited condition that may occur in up to 75% of normal pubertal boys. Adolescent gynecomastia typically resolves within 2 years but may not totally resolve if the degree of gynecomastia is extreme. Gynecomastia may sometimes occur as part of Klinefelter syndrome, or it may occur in boys who are taking drugs such as antidepressants or marijuana. Therapy, either medical (antiestrogens or aromatase inhibitors) or surgical, should be considered in prolonged or severe cases (see Chapter 3).

TESTICULAR TUMORS

Most malignant tumors of the testis are seminomas and teratomas. Seminomas are rare in childhood; they may be hormone-producing. The major hormone-producing tumor of the testis is the Leydig cell tumor. It is often associated with sexual precocity. Other testicular tumors (choriocarcinomas and dysgerminomas) have been reported in association with sexual precocity. Treatment of testicular tumors is surgical removal; chemotherapy and radiation therapy are not used in childhood unless there is high-grade malignancy or metastases. The prognosis in patients with Leydig cell tumors is generally good.

ADRENAL CORTEX

The adult adrenal cortex has a regional distribution of terminal steroid production. The outermost zona glomerulosa is the predominant source of aldosterone. The middle zona fasciculata makes cortisol and small amounts of mineralocorticoids. The innermost zona reticularis produces mainly androgens and estrogens. A fetal zone, or provisional cortex, that predominates during fetal development produces glucocorticoids, mineralocorticoids, androgens, and estrogens. The fetal zone is relatively deficient in 3β-ol dehydrogenase (see Figure 32–6); hence placently produced progesterone is the major precursor used in fetal adrenal production of cortisol and aldosterone.

The adrenal cortical production of cortisol is under the control of pituitary adrenocorticotropic hormone (ACTH; see Figure 32–1 and Table 32–1), which is in turn regulated by the hypothalamic peptide, corticotropin-releasing hormone (CRH). The complex interaction of CNS influences on CRH secretion, coupled with negative feedback of serum cortisol, leads to a diurnal pattern of ACTH and cortisol release. ACTH concentration is greatest during the early morning hours with a smaller peak in the late afternoon and a nadir at night. The pattern of serum cortisol concentration follows this pattern with a lag of a few hours. In the absence of cortisol feedback, there is dramatic CRH and ACTH hypersecretion.

Glucocorticoids are critical for gene expression in a many cell types. In excess, glucocorticoids are both catabolic and antianabolic; that is, they promote the release of amino acids from muscle and increase gluconeogenesis while decreasing incorporation of amino acids into muscle protein. They also antagonize insulin activity and facilitate lipolysis. Glucocor-
ADRENOCORTICAL INSUFFICIENCY (ADRENAL CRISIS, ADDISON DISEASE)

The leading causes of adrenal insufficiency are hereditary enzyme defects (congenital adrenal hyperplasia), autoimmune destruction of the glands (Addison disease), central adrenal insufficiency caused by intracranial neoplasm or its treatment, or congenital midline defects associated with optic nerve hypoplasia (septo-optic dysplasia). A rare form of familial adrenal insufficiency occurs in association with cerebral sclerosis and spastic paraplegia (adrenoleukodystrophy). Addison disease may be familial and has been described in association with hypoparathyroidism, candidiasis, hypothyroidism, pernicious anemia, hypogonadism, and diabetes mellitus as one of the polyglandular autoimmune syndromes. Less commonly, the gland is destroyed by tumor, calcification, or hemorrhage (Waterhouse-Friderichsen syndrome). Adrenal disease secondary to opportunistic infections (fungal or tuberculous) is reported in AIDS. In children, central adrenal insufficiency due to anterior pituitary tumor is rare. A temporary salt-losing disorder resulting from partial mineralocorticoid deficiency or renal underresponsiveness (pseudohypoaldosteronism) may occur during infancy or with pylonephritis.

Acute illness, surgery, trauma, or hyperthermia may precipitate an adrenal crisis in patients with adrenal insufficiency. Patients with primary adrenal insufficiency are at greater risk for life-threatening crisis than patients with central ACTH deficiency because mineralocorticoid secretion and low-level autonomous cortisol secretion remain intact in central ACTH deficiency.

Clinical Findings

A. Symptoms and Signs

1. Acute form (adrenal crisis)  Manifestations include nausea, vomiting, diarrhea, abdominal pain, dehydration, fever (sometimes followed by hypothermia), weakness, hypotension, circulatory collapse, confusion and coma. Increased pigmentation may be associated with primary adrenal insufficiency caused by melanocyte-stimulating activity of the hypersecreted parent molecule, ACTH.

2. Chronic form  Manifestations include fatigue, hypotension, weakness, failure to gain weight, loss of appetite, salt craving (primary insufficiency), vomiting, and dehydration. Diffuse tanning with increased pigmentation over pressure points, scars, and mucous membranes may be present in primary adrenal insufficiency. A small heart may be seen on chest radiograph.

B. Laboratory Findings

1. Suggestive of adrenocortical insufficiency  In primary adrenal insufficiency, serum sodium and bicarbonate levels, arterial partial pressure of carbon dioxide, blood pH, and blood volume are decreased. Serum potassium and urea nitrogen levels are increased. Urinary sodium level and the ratio of urinary sodium to potassium are inappropriate for the degree of hyponatremia. In central adrenal insufficiency, serum sodium levels may be mildly decreased as a result of impaired water excretion. Eosinophilia and moderate lymphopenia occur in both forms of insufficiency.

2. Confirmatory tests

a. ACTH (cosyntropin) stimulation test  In primary adrenal insufficiency (originating in the gland itself), plasma cortisol and aldosterone concentrations do not increase significantly over baseline 60 minutes after an intravenous dose of ACTH (250 mcg). To diagnose central adrenal insufficiency, a low dose of ACTH is given (1 mcg).

b. Baseline serum ACTH concentration  Values are elevated in primary adrenal failure and low in central adrenal insufficiency.

c. Urinary free cortisol and 17-hydroxycorticosterone excretion  Values are decreased.

d. CRH test  This test assesses responsiveness of the entire hypothalamic-pituitary-adrenal axis. After administration of ovine CRH, serum concentrations of ACTH and cortisol are measured over 2 hours. Verification of an intact axis or localization of the site of impairment is possible with careful interpretation of results.

Differential Diagnosis

Acute adrenal insufficiency must be differentiated from severe acute infections, diabetic coma, various disturbances of the CNS, and acute poisoning. In the neonatal period, adrenal insufficiency may be clinically indistinguishable from respiratory distress, intracranial hemorrhage, or sepsis. Chronic adrenocortical insufficiency must be differentiated from anorexia nervosa, certain muscular disorders (myasthenia gravis), salt-losing nephritis, and chronic debilitating infections, and must be considered in cases of recurrent spontaneous hypoglycemia.
CHAPTER 32

Treatment

A. Acute Insufficiency (Adrenal Crisis)

1. Hydrocortisone sodium succinate—Hydrocortisone sodium succinate is given intravenously at a dose of 50 mg/m² intravenously over 2–5 minutes or intramuscularly; thereafter, it is given intravenously, 12.5 mg/m², every 4–6 hours until stabilization is achieved and oral therapy can be tolerated.

2. Fluids and electrolytes—In primary adrenal insufficiency, 5–10% glucose in normal saline, 10–20 mL/kg intravenously, is given over the first hour and repeated if necessary to reestablish vascular volume. Normal saline is continued thereafter at 1½–2 times the maintenance fluid requirements. Intravenous boluses of glucose (10% glucose, 2 mL/kg) may be needed every 4–6 hours to treat hypoglycemia. In central adrenal insufficiency, routine fluid management is generally adequate after restoration of vascular volume and institution of cortisol replacement.

3. Fludrocortisone—When oral intake is tolerated, fludrocortisone, 0.05–0.15 mg daily, is started and continued as necessary every 12–24 hours for primary adrenal insufficiency.

4. Inotropic agents—Rarely, inotropic agents such as dopamine and dobutamine are needed. However, adequate cortisol replacement is critical because pressor agents may be ineffective in adrenal insufficiency.

5. Waterhouse-Friderichsen syndrome with fulminant infections—The use of adrenocorticosteroids and norepinephrine in the treatment or prophylaxis of fulminant infections remains controversial. Corticosteroids may augment the generalized Shwartzman reaction in fatal cases of meningococcemia. However, corticosteroids should be considered if there is possible adrenal insufficiency, particularly if there is hypotension and circulatory collapse.

B. Maintenance Therapy

Following initial stabilization, the most effective substitution therapy is hydrocortisone, combined with fludrocortisone in primary adrenal insufficiency. Overtreatment should be avoided as it causes obesity, growth retardation, and other cushingoid features. Additional hydrocortisone, fludrocortisone, or sodium chloride, singly or in combination, may be necessary with acute illness, surgery, trauma, or other stress reactions. Supportive adrenocortical therapy should be given whenever surgical operations are performed in patients who have at some time received prolonged therapy with adrenocorticosteroids.

1. Glucocorticoids—A maintenance dosage of 6–10 mg/m²/d of hydrocortisone (or equivalent) is given orally in two or three divided doses. The dosage of all glucocorticoids is increased to 30–50 mg/m²/d during intercurrent illnesses or other times of stress.

2. Mineralocorticoids—In primary adrenal insufficiency, fludrocortisone is given, 0.05–0.15 mg orally daily as a single dose or in two divided doses. Periodic monitoring of blood pressure is recommended to avoid overdosing.

3. Salt—The child should be given ready access to table salt. Frequent blood pressure determinations in the recumbent position should be made to check for hypertension. In the infant, supplementation of 3–5 mEq Na⁺/kg/d by adding the injectable solution (4 mg/mL) to formula or breast milk is generally required until table foods are introduced.

C. Corticosteroids in Patients with Adrenocortical Insufficiency Who Undergo Surgery

1. Before operation—Hydrocortisone sodium succinate, 30–50 mg/m²/d intravenously 1 hour before surgery.

2. During operation—Hydrocortisone sodium succinate, 25–100 mg intravenously with 5–10% glucose in saline throughout surgery.

3. During recovery—Hydrocortisone sodium succinate, 12.5 mg/m² intravenously every 4–6 hours until oral doses are tolerated. The oral dose of three to five times the maintenance dose is continued until the acute stress is over, at which time the patient can be returned to the maintenance dose.

Course & Prognosis

The course of acute adrenal insufficiency is rapid, and death may occur within a few hours, particularly in infants, unless adequate treatment is given. Spontaneous recovery is unlikely. Patients who have received long-term treatment with adrenocorticosteroids may exhibit adrenal collapse if they undergo surgery or other acute stress. Pharmacologic doses of glucocorticoids during these episodes may be needed throughout life. In all forms of acute adrenal insufficiency, the patient should be observed carefully once the crisis has passed and evaluated with laboratory tests to assess the degree of permanent adrenal insufficiency.

Patients with chronic adrenocortical insufficiency who receive adequate therapy can lead normal lives.

CONGENITAL ADRENAL HYPERPLASIAS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Genital virilization in females, with labial fusion, urogenital sinus, enlargement of the clitoris, or other evidence of androgen action.
- Salt-losing crises in infant males or isosexual precocity in older males with infantile testes.
- Increased linear growth and advanced skeletal maturation.
Elevation of plasma 17-hydroxyprogesterone concentrations in the most common form; may be associated with hyponatremia, hyperkalemia, and metabolic acidosis, particularly in newborns.

**General Considerations**

Autosomal recessive mutations in the enzymes of adrenal steroidogenesis in the fetus cause abnormal cortisol biosynthesis with increased ACTH secretion. ACTH excess subsequently results in adrenal hyperplasia with increased production of adrenal hormone precursors, including androgens. Increased pigmentation, especially of the scrotum, labia majora, and nipples, is common with excessive ACTH secretion. Congenital adrenal hyperplasia (CAH) is most commonly (> 80% of patients) the result of homozygous 21-hydroxylase (cytochrome P-450 C21) deficiency (see Figure 32–6). In its severe form, excess adrenal androgen production starting in the first trimester of fetal development causes virilization of the female fetus and life-threatening hypovolemic, hyponatremic shock (adrenal crisis) in the newborn. Other enzyme defects that less commonly result in CAH include 11-hydroxylase, 3β-ol dehydrogenase, 20,22-desmolase, 18-hydroxylation-17, and 22-desmolase deficiencies. The clinical syndromes associated with these defects are shown in Figure 32–6 and Table 32–11.

Studies of patients with 21-hydroxylase deficiency indicate that the clinical type (salt-wasting or non–salt-wasting) is usually consistent within a kindred and that a close genetic linkage exists between the 21-hydroxylase gene and the human leukocyte antigen complex on chromosome 6. The latter finding has allowed more precise heterozygote detection and prenatal diagnosis. Population studies indicate that the defective gene is present in 1:250–1:100 people and that the incidence of the disorder is 1:15,000–1:5000. Mass screening for this enzyme defect, using a microfilter paper technique to measure serum 17-hydroxyprogesterone, has been established in some U.S. states.

Nonclassic presentations of 21-hydroxylase deficiency have been reported with increasing frequency. Affected persons have a normal phenotype at birth but develop evidence of virilization during later childhood, adolescence, or early adulthood. In these cases, previously referred to as late-onset or acquired enzyme deficiency, results of hormonal studies are characteristic of 21-hydroxylase deficiency. An asymptomatic form has also been identified in which individuals have none of the phenotypic features of the disorder, but have hormonal study results identical to patients with nonclassic 21-hydroxylase deficiency. The nonclassic form appears to be less severe than the classic form. Because members of the same family may have classic, nonclassic, and asymptomatic forms, the disorders may be due to allelic variations of the same enzyme.

**Table 32–11.** Clinical and laboratory findings in adrenal enzyme defects resulting in congenital adrenal hyperplasia.

*Children with "simple virilizing (non–salt-wasting)" forms of 21-hydroxylase deficiency congenital adrenal hyperplasia (CAH) may have normal aldosterone production and serum electrolytes, but some children have normal aldosterone production and serum electrolytes at the expense of elevated plasma renin activity and are, by definition, compensated salt-wasters. These children usually receive mineralocorticoid as well as glucocorticoid treatment. Children with 21-hydroxylase deficiency CAH should therefore have documented normal plasma renin activity in addition to normal serum electrolytes before they are considered non–salt-wasters.

DHEA, dehydroepiandrosterone; 17-OHP, 17-hydroxyprogesterone.
CHAPTER 32

Clinical Findings

A. Symptoms and Signs

1. In females—Abnormality of the external genitalia varies from mild enlargement of the clitoris to complete fusion of the labioscrotal folds, forming a scrotum, a penile urethra, a penile shaft, and with clitoral enlargement sufficient to form a normal-sized glans (see Table 32–8). Signs of adrenal insufficiency (salt loss) may occur in the first days of life but more typically appear in the first or second week. Rarely, adrenal insufficiency does not occur for months or years. With milder enzyme defects, salt loss may not occur, and virilization predominates (simple virilizing form). In untreated non–salt-losing 21-hydroxylase or 11-hydroxylase deficiency, growth rate and skeletal maturation are accelerated and patients appear muscular. Pubic hair appears early (often before the second birthday), acne may be excessive, and the voice may deepen. Excessive pigmentation may develop. Final adult height is often compromised.

2. In males—The male infant usually appears normal at birth but may present with salt-losing crisis in the first 2–4 weeks of life. In milder forms, salt-losing crises may not occur. In this circumstance, enlargement of the penis and increased pigmentation may be noted during the first few months. Other symptoms and signs are similar to those of affected females. The testes are not enlarged except in the rare male in whom aberrant adrenal cells (adrenal rests) are present in the testes, producing unilateral or asymmetrical bilateral enlargement. In the rare isolated defect of 17,20-desmolase activity, ambiguous genitalia may be present because of impaired androgen production (see Figure 32–6).

B. Laboratory Findings

1. Blood—Hormonal studies are essential for accurate diagnosis. Findings characteristic of the enzyme deficiencies are shown in Table 32–11.

2. Genetic studies—Rapid chromosomal diagnosis should be obtained in any newborn with ambiguous genitalia.

C. Imaging

Adrenal ultrasonography, CT scanning, and MRI may be useful in defining pelvic anatomy or enlarged adrenals or in localizing an adrenal tumor. Contrast-enhanced radiographs of the vagina and pelvic ultrasonography may be helpful in delineating the internal anatomy in a newborn with ambiguous genitalia.

Treatment

A. Medical Treatment

Treatment goals in CAH are normalization of growth velocity and skeletal maturation with the smallest dose of glucocorticoid that can suppress adrenal function. Excessive glucocorticoids cause the undesirable side effects of Cushing syndrome. Mineralocorticoid replacement sustains normal electrolyte homeostasis, but excessive mineralocorticoids cause hypertension.

1. Glucocorticoids—Initially, parenteral or oral hydrocortisone (30–50 mg/m²/d) suppresses abnormal adrenal steroidogenesis within 2 weeks. When adrenal suppression has been accomplished, as evidenced by normalization of serum 17-hydroxyprogesterone, patients are placed on maintenance doses of 15–20 mg/m²/d in two or three divided doses. Between 50% and 60% of the daily dose should be given in the late evening to suppress early morning ACTH rise. Dosage is adjusted to maintain normal growth rate and skeletal maturation. Various serum and urine androgens have been used to monitor therapy, including 17-hydroxyprogesterone, androstenedione, and urinary pregnanetriol. No one test is universally accepted. In adolescent girls, normal menses are a sensitive index of the adequacy of therapy. Therapy should be continued throughout life in both males and females because of the possibility of malignant degeneration of the hyperplastic adrenal gland. In pregnant females with CAH, suppression of adrenal androgen secretion is critical to avoid virilization of the fetus, particularly a female fetus.

2. Mineralocorticoids—Fludrocortisone, 0.05–0.15 mg, is given orally once a day or in two divided doses. Periodic monitoring of blood pressure and plasma renin is recommended to adjust dosing.

B. Surgical Treatment

For affected females, consultation with a urologist experienced in female genital reconstruction should be arranged as soon as possible during infancy.

Course & Prognosis

When therapy is initiated in early infancy, abnormal metabolic effects and progression of masculinization can be avoided. Treatment with glucocorticoids permits normal growth, development, and sexual maturation. If not adequately controlled, CAH results in sexual precocity and masculinization throughout childhood. Affected individuals will be tall as children but short as adults because of a rapid rate of skeletal maturation and premature closure of the epiphyses. If treatment is delayed or inadequate until somatic development is completed (12–14 years as determined by bone age), true central sexual precocity may occur in males and females.

Patient education stressing lifelong therapy is important to ensure compliance in adolescence and later life. Virilization and multiple surgical genital reconstructions are associated with a high risk of psychosexual disturbances in female patients. Ongoing psychological evaluation and support is a critical component of care.
ADRENOCORTICAL HYPERFUNCTION
(CUSHING DISEASE, CUSHING SYNDROME)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Truncal adiposity, thin extremities, moon facies, muscle wasting, weakness, plethora, easy bruising, purple striae, decreased growth rate, and delayed skeletal maturation.
- Hypertension, osteoporosis, and glycosuria.
- Elevated serum corticosteroids, low serum potassium, eosinopenia, and lymphopenia.

General Considerations

Cushing syndrome may result from excessive secretion of adrenal steroids autonomously (adenoma or carcinoma), excess pituitary ACTH secretion (Cushing disease), ectopic ACTH secretion, or chronic exposure to exogenous glucocorticoid medications. In children younger than 12 years, Cushing syndrome is usually iatrogenic (secondary to exogenous ACTH or glucocorticoids). It may rarely be due to adrenal tumor, adrenal hyperplasia, pituitary adenoma, or extrapituitary ACTH-producing tumor.

Clinical Findings

A. Symptoms and Signs

1. Excess glucocorticoid—Manifestations include adiposity, most marked on the face, neck, and trunk (a fat pad in the interscapular area is characteristic); fatigue; plethoric facies; purplish striae; easy bruising; osteoporosis; hypertension; glucose intolerance; back pain; muscle wasting and weakness; and marked retardation of growth and skeletal maturation.

2. Excess mineralocorticoid—Patients have hypokalemia, mild hypernatremia with water retention, increased blood volume, edema, and hypertension.

3. Excess androgen—Hirsutism, acne, and varying degrees of virilization are present. Menstrual irregularities occur in older girls.

B. Laboratory Findings

1. Blood

a. Plasma cortisol—Values are elevated, with loss of normal diurnal variation. Determination of cortisol level between midnight and 2 AM may be a sensitive indicator of the loss of diurnal variation.

B. Serum chloride and potassium—Both values are usually low, but serum sodium and bicarbonate concentrations may be elevated with metabolic alkalosis.

C. Serum ACTH—ACTH concentration is decreased in adrenal tumor and increased with ACTH-producing pituitary or extrapituitary tumors.

D. CBC—Polymorphonuclear leukocytosis with lymphopenia and eosinopenia are common. Polycythemia occurs.

2. Salivary cortisol—This is a less invasive means by which to measure serial cortisol values, and the tests may be performed at home. Salivary cortisol obtained at midnight is a highly specific and sensitive test for hypercortisolism.

3. 24-Hour urinary free cortisol excretion—This value is elevated. It is considered the most useful initial test to document hypercortisolism, although midnight salivary cortisol is considered a reasonable and more practical alternative.

4. Response to dexamethasone suppression testing—The suppression of adrenal function by a small dose (0.5 mg) of dexamethasone is reduced in adrenal hyperfunction; larger doses (4–16 mg/d in four divided doses) of dexamethasone cause suppression of adrenal activity when the disease is due to ACTH hypersecretion, whereas hypercortisolism due to adenomas and adrenal carcinomas is rarely suppressed.

5. CRH test—The CRH stimulation test, in conjunction with petrosal sinus sampling, is effective in distinguishing pituitary and ectopic sources of ACTH excess and for lateralization of pituitary sources prior to surgery.

C. Imaging

Pituitary imaging may demonstrate a pituitary adenoma. Adrenal imaging by CT scan may demonstrate adenoma or bilateral hyperplasia. Radionuclide studies of the adrenals may be useful in complex cases. Osteoporosis, evident first in the spine and pelvis, with compression fractures may occur in advanced cases. Skeletal maturation is usually delayed.

Differential Diagnosis

Children with exogenous obesity accompanied by striae and hypertension are often suspected of having Cushing syndrome. The child’s height, growth rate, and skeletal maturation are helpful in differentiating the two. Children with Cushing syndrome have a poor growth rate, relatively short stature, and delayed skeletal maturation, while those with exogenous obesity usually have a normal or slightly increased growth rate, normal to tall stature, and advanced skeletal maturation. The color of the striae (purplish in Cushing syndrome, pink in obesity) and the distribution of the obesity assist in differentiation. The urinary free cortisol excretion (in milligrams per gram of creatinine) may be mildly elevated in obesity, but midnight salivary cortisol is normal.
Treatment

In all cases of primary adrenal hyperfunction due to tumor, surgical removal, is indicated if possible. Glucocorticoids should be administered parenterally in pharmacologic doses during and after surgery until the patient is stable. Supplemental oral glucocorticoids, potassium, salt, and mineralocorticoids may be necessary until the suppressed contralateral adrenal gland recovers, sometimes over a period of several months. The use of mitotane, a DDT derivative that is toxic to the adrenal cortex, and aminoglutethimide, an inhibitor of steroid synthesis, have been suggested, but their efficacy in children with adrenal tumors has not been determined. Pituitary microadenomas may respond to pituitary surgery or irradiation.

Prognosis

If the tumor is malignant, the prognosis is poor if it cannot be completely removed. If it is benign, cure is to be expected following proper preparation and surgery.

Primary Hyperaldosteronism

Primary hyperaldosteronism may be caused by an adrenal adenoma or adrenal hyperplasia. It is characterized by paresthesias, tetany, weakness, nocturnal enuresis, periodic paralysis, low serum potassium and elevated serum sodium levels, hypertension, metabolic alkalosis, and production of large volume, alkaline urine with low specific gravity. The specific gravity does not respond to vasopressin. Glucose tolerance test is frequently abnormal. Plasma and urinary aldosterone are elevated. In contrast to renal disease or Bartter syndrome, plasma renin activity is suppressed, creating a high aldosterone-to-renin ratio. In patients with adrenal tumor, ACTH may further increase the excretion of aldosterone. Marked improvement after the administration of an aldosterone antagonist such as spironolactone may be of diagnostic value.

Treatment is with glucocorticoids (glucocorticoid remediable hyperaldosteronism or familial hyperaldosteronism type 1), spironolactone (familial hyperaldosteronism type 2), or subtotal or total adrenalectomy for hyperplasia, and surgical removal if a tumor is present.

Actions

Glucocorticoids exert a direct or permissive effect on virtually every tissue of the body; major known effects include the following:

1. Gluconeogenesis in the liver
2. Stimulation of fat breakdown (lipolysis) and redistribution of body fat
3. Catabolism of protein with an increase in nitrogen and phosphorus excretion
4. Decrease in lymphoid and thymic tissue and a decreased cellular response to inflammation and hypersensitivity
5. Alteration of CNS excitation
6. Retardation of connective tissue mitosis and migration; decreased wound healing
7. Improved capillary tone and increased vascular compartment volume and pressure

Side Effects of Therapy

When prolonged use of pharmacologic doses of glucocorticoids is necessary, clinical manifestations of Cushing syndrome are common. Side effects may occur with the use of synthetic exogenous agents by any route, including inhalation and topical administration, or with the use of ACTH. Use of a larger dose of glucocorticoids given once every 48 hours (alternate-day therapy) lessens the incidence and severity of some of the side effects (Table 32–13).

Tapering of Pharmacologic Doses of Steroids

Prolonged use of pharmacologic doses of glucocorticoids causes suppression of ACTH secretion and consequent adrenal atrophy. The abrupt discontinuation of glucocorticoids may result in adrenal insufficiency. ACTH secretion generally does not restart until the administered steroid has been given in subphysiologic doses (< 6 mg/m²/d orally) for several weeks.

If tapering is necessary in treating the condition for which the glucocorticoid is prescribed, a reduction of 25–50% every 2–7 days is sufficiently rapid to permit observation of clinical symptomatology. An alternate-day schedule (single dose given every 48 hours) will allow for a 50% decrease in the total 2-day dosage while providing the desired pharmacologic effect. If tapering is not required for the underlying disease, the dosage can be rapidly decreased safely to the physiologic range. Although a rapid decrease in dose to the physiologic range will not lead to frank adrenal insufficiency (because adequate exogenous cortisol is being provided), some patients may experience a steroid withdrawal syndrome, characterized by malaise, insomnia, fatigue, and loss of appetite. These symptoms may necessitate a two- or three-step decrease in dose to the physiologic range.

Once a physiologic equivalent dose (8–10 mg/m²/d hydrocortisone or equivalent) is achieved and the patient’s underlying disease is stable, the dose can be decreased to 4–5 mg/m²/d given only in the morning. This will allow the adrenal axis to recover. After this dose has been given for 4–6 weeks, assessment of endogenous adrenal activity is estimated by obtaining fasting plasma cortisol concentrations between 7 and 8 AM prior to the morning steroid dose or by a low-dose ACTH stimulation test (1 mcg cosyntropin fol-
followed by measurement of cortisol after 45–60 minutes). When an alternate-day schedule is followed, plasma cortisol is measured the morning before treatment. Plasma cortisol concentration in the physiologic range (> 10 mg/dL) indicates return of basal physiologic adrenal rhythm. Exogenous steroids may then be discontinued safely, although it is advisable to continue giving stress doses of glucocorticoids when appropriate until recovery of the response to stress has been documented.

After basal physiologic adrenal function returns, the adrenal reserve or capacity to respond to stress and infection can be estimated by the low-dose ACTH stimulation test, in which 1 mcg of synthetic ACTH (cosyntropin) is administered intravenously. Plasma cortisol is measured prior to (zero time) and at 45–60 minutes after the infusion. A plasma cortisol concentration greater than 18 mg/dL at 60 minutes indicates a satisfactory adrenal reserve.

Even if the results of testing are normal, patients who have received prolonged treatment with glucocorticoids may develop signs and symptoms of adrenal insufficiency during acute stress, infection, or surgery for months to years after treatment has been stopped. Careful monitoring, and the use of stress doses of glucocorticoids, should be considered during severe illnesses and surgery.

ADRENAL MEDULLA PHEOCHROMOCYTOMA

Pheochromocytoma is uncommon and only 10% of the reported cases occur in pediatric patients. The tumor can be located wherever chromaffin tissue (adrenal medulla, sympathetic ganglia, or carotid body) is present, possibly from decreased apoptosis of neural crest cells during development. It may be multiple, recurrent, and sometimes malignant. Familial forms include pheochromocytomas associated with the dominantly inherited neurofibromatosis type 1, MEN type 2, and von Hippel-Lindau syndromes, as well as mutations of the succinate dehydrogenase genes. Neuroblastomas, ganglioneuromas, and other neural tumors, as well as carcinoid tumors may secrete pressor amines and mimick pheochromocytoma.

The symptoms of pheochromocytoma are generally caused by excessive secretion of epinephrine or norepinephrine and most commonly include headache, sweating, tachycardia, and hypertension. Other symptoms are anxiety, hypertension, dizziness, weakness, nausea and vomiting, diarrhea, dilated pupils, blurred vision, abdominal and precordial pain, and vasomotor instability (flushing and postural hypotension). Sustained symptoms may lead to cardiac, renal, optic, or cerebral damage.

Laboratory diagnosis is possible in more than 90% of cases. Serum and urine catecholamines are elevated, but abnormalities may be limited periods of symptomatology or paroxysm. Plasma free metanephrine level (phenoxybenzamine, tricyclic antidepressants, and β-adrenoreceptor blockers can create false-positive results) is the most sensitive test and the gold standard for diagnosis. Levels three times the normal range are diagnostic. Intermediate values may require additional testing, with urinary vanillylmandelic acid and urinary total metanephrines providing the highest specificity. Provocative tests using histamine, tyramine, or glucagon and the phentolamine tests may be abnormal but are dangerous and are rarely necessary. After demonstrating a tumor biochemically, imaging methods including CT or MRI are used to localize the tumor. When available, functional ligands such as (123)I-MIBG, [18F]DA positron emission tomography scanning and somatostatin receptor scintigraphy (with either [123]I-Tyr3-octreotide or [111In]DTPA-octreotide) are useful in further diagnostic evaluation.

Laparoscopic tumor removal is the treatment of choice; however, the procedure must be undertaken with great caution and with the patient properly stabilized. Oral phenoxybenzamine or intravenous phentolamine is used preoperatively. Profound hypotension may occur as the tumor is removed but may be controlled with an infusion of norepinephrine, which may have to be continued for 1–2 days.

Unless irreversible secondary vascular changes have occurred, complete relief of symptoms is to be expected after recovery from removal of a benign tumor. However, prognosis is poor in patients with metastases, which occur more commonly with large, extra-adrenal pheochromocytomas.
Diabetes Mellitus

H. Peter Chase, MD
George S. Eisenbarth, MD, PhD

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Polyuria, polydipsia, and weight loss.
- Hyperglycemia and glucosuria with or without ketonuria.

GENERAL CONSIDERATIONS

Type 1 diabetes or immune-mediated diabetes (previously called juvenile diabetes or insulin-dependent diabetes mellitus [IDDM]) is the most common type of diabetes in people younger than age 40 years. It is associated with islet cell antibodies (immunologic markers), diminished insulin production, and being ketosis-prone.

Type 2 diabetes (non–insulin-dependent diabetes mellitus [NIDDM], non–immune-mediated) is the most common type in persons older than age 40 years; it is associated with being overweight, insensitivity to insulin, and not being prone to ketosis. Type 2 diabetes is increasing in frequency in children and is found in up to half of black and Hispanic children and in over two thirds of American Indian children who develop diabetes. It occurs most frequently in overweight teenagers.

Maturity-onset diabetes of youth (MODY) is much less common and comprises several forms of diabetes in non-obese children with identified genetic mutations (eg, mutations of glucoinase or hepatic nuclear factor 1 or 2 genes). It presents as a nonketotic form of diabetes without islet cell antibodies and often is associated with a family history of diabetes in several generations.

Neonatal diabetes, which is rare, is associated with several distinct etiologies that require specialty evaluation and specific therapies. For example, some children have transient neonatal diabetes. Others have specific mutations and are best treated with sulfonylurea medications after receiving initial insulin therapy.

Pathogenesis

A. Type 1 Diabetes

Type 1 diabetes results from immunologic damage to the insulin-producing β-cells of the pancreatic islets. This damage occurs gradually—over months or years in most people—and symptoms do not appear until about 90% of the pancreatic islets have been destroyed. The immunologic damage requires a genetic predisposition and is probably influenced by environmental factors.

The importance of genetics is shown by the fact that among identical twins, more than 50% of second twins develop diabetes after the first twin develops the disease. About 6% of siblings or offspring of persons with type 1 diabetes also develop diabetes (compared with prevalence in the general population of 0.2–0.3%). The condition is more common in white children but occurs in all racial groups. There is an association with human leukocyte antigen (HLA)-DR3 and HLA-DR4, and about 95% of white diabetic children have at least one of these HLA types. Forty percent have both HLA-DR3 and HLA-DR4 (one from each parent), compared with only 3% of the general population.

The importance of environmental factors is suggested because not all second identical twins develop diabetes. Important environmental factors may be viral infections or factors in the diet.

The immunologic basis of diabetes is demonstrated by the ability of cyclosporin, a potent immunosuppressive agent, to preserve islet tissue for 1–2 years when given to newly diagnosed patients. However, renal damage from cyclosporin precludes its use. White blood cells are found in the islets of newly diagnosed patients and may release toxic products (free radicals, interleukin-1, and tumor necrosis factor) that injure the islets. Antibodies to islet cells, insulin, glutamic acid decarboxylase, ICA512 (IA-2), and other antigens are present for months to years prior to diagnosis in the serum of over 90% of patients who will develop type 1 diabetes. These antibodies are probably the effect and not the cause of islet β-cell destruction.
B. Type 2 Diabetes

Type 2 diabetes has a strong genetic component, although the inherited defects vary in different families. Obesity (particularly central) and lack of exercise are often major environmental contributing factors. Insulin insensitivity results from all of these circumstances. The prevalence is increased among females, which may be related to its association with the polycystic ovary syndrome. Acanthosis nigricans, a thickening and darkening of the skin over the posterior neck, armpits, or elbows, may aid in the diagnosis of type 2 diabetes.

► Prevention

A. Type 1 Diabetes

Free antibody screening is now available for families having a relative with type 1 diabetes (1-800-425-8361). Intervention trials on antibody-positive first-degree relatives have begun in an effort to try to prevent type 1 diabetes.

B. Type 2 Diabetes

The prevention of type 2 diabetes was evaluated in a large study, the Diabetes Prevention Program. The study found that 30 minutes of exercise per day (5 days/wk) and a low-fat diet reduced the risk of diabetes by 58%. Taking metformin also reduced the risk of type 2 diabetes by 31%.

► Clinical Findings

The classic symptoms of polyuria, polydipsia, and weight loss are now so well recognized that friends or family members often suspect the diagnosis of type 1 diabetes in affected individuals. Other cases may be detected by finding glucosuria on routine office urinalysis. Up to 50% of new cases of diabetes used to be diagnosed in patients presenting in coma, but most are now diagnosed before the individuals develop severe ketonuria, ketonemia, and secondary acidosis. Children often have a preceding minor illness, such as a flu-like episode. Blood or urine glucose levels can be checked in a few seconds, which could be life-saving. No disease other than diabetes (mellitus or insipidus) presents with continued frequent urination in spite of a dry tongue. An oral glucose tolerance test is rarely necessary in children. A random blood glucose level above 300 mg/dL (16.6 mmol/L) or a fasting blood glucose level above 200 mg/dL (11 mmol/L) is sufficient to make the diagnosis of diabetes. The 1997 revised guidelines for the diagnosis of diabetes (see references) are a fasting plasma glucose level over 126 mg/dL (7 mmol/L) or a plasma glucose level above 200 mg/dL (11.1 mmol/L) taken randomly (with symptoms of diabetes) or 2 hours after an oral glucose load (1.75 g glucose/kg up to a maximum of 75 g). Confirmation of such abnormalities on more than one occasion is recommended as transient hyperglycemia can occur, particularly with illness. Impaired (not yet diabetic) fasting glucose values are 100–125 mg/dL (5.5–6.9 mmol/L) and impaired 2-hour values are 140–200 mg/dL (7.8–11.1 mmol/L). If the presentation is mild, hospitalization is usually not necessary.

► Treatment

Most children have type 1 diabetes. The five major variables in treatment are (1) insulin type and dosage, (2) diet, (3) exercise, (4) stress management, and (5) blood glucose and ketone monitoring. All must be considered to obtain safe and effective metabolic control. Although teenagers can be taught to perform many of the tasks of diabetes management, they do better when supportive—not overbearing—parents continue to be involved in management of their disease. Children younger than age 10 or 11 years cannot reliably administer insulin without adult supervision because they lack fine motor control and may not understand the importance of accurate dosage.

A. Patient and Family Education

Education about diabetes for all family members is essential for the home management of diabetes. The use of an educational book (see Understanding Diabetes in the references) can be very helpful to the family. All caregivers need to learn about diabetes, how to give insulin injections, perform home blood glucose monitoring, and handle acute complications. The stress imposed on the family around the time of initial diagnosis may lead to feelings of shock, denial, sadness, anger, fear, and guilt. Meeting with a counselor to express these feelings at the time of diagnosis helps with long-term adaptation.

A. Insulin

Insulin has three key functions: (1) it allows glucose to pass into the cell; (2) it decreases the physiologic production of glucose, particularly in the liver; and (3) it turns off ketone production.

1. Treatment of new-onset diabetes—The greater the acidemia and ketone production, the greater the amount of insulin needed. If ketonemia is significant, venous blood pH is low (< 7.30), and the patient is dehydrated, intravenous insulin and fluid therapy should be given (see later discussion of ketonuria, ketonemia, and ketoacidosis). If the child is adequately hydrated and has a normal venous blood pH, one or two intramuscular or subcutaneous injections of 0.1–0.2 U/kg of regular insulin—or preferably of insulin lispro (Humalog, [H]) or insulin aspart (NovoLog, [NL])—1 hour apart will help shut down ketone production. If ketone production is insignificant or absent, this regimen is not necessary, and routine subcutaneous injections can be started.

When ketones are not present, the child is usually more responsive to insulin, and a total daily dosage of 0.25–0.5 U/kg is often given, with adjustments as needed. If ketones are or were present, the child usually does not produce as much insulin and will require 0.5–1 U/kg of total insulin per 24 hours.
Children usually receive mixtures of a rapid-acting insulin (to cover food intake or high blood glucose) and a longer-acting insulin (to suppress endogenous hepatic glucose production). This is achieved by combining insulins of different formulations with the desired properties (Table 33–1). The dosages are adjusted with each injection during the first week. In the past, most physicians began treatment of newly diagnosed children with two injections per day of an intermediate-acting insulin (eg, NPH) and a rapid-acting insulin such as Humalog or NovoLog (H or NL). About two thirds of the total dosage is usually given before breakfast and the remainder before dinner. If human regular insulin is used, the injections are given 30–60 minutes before meals; when using H or NL as the rapid-acting insulin, the injections are given 10–15 minutes before eating. In young children who eat irregular amounts of food, it is often helpful to wait until after the meal to give the injection and decide on the appropriate dose of H or NL. Children younger than age 4 years usually need 1 or 2 units of rapid-acting insulin to cover meals; the remainder of the dosage is NPH insulin. Children aged 4–10 years may require up to 4 units of rapid-acting insulin to cover breakfast and dinner, whereas proportionately higher doses (usually 4–10 units) of H or NL or regular insulin are used for older children.

An alternative approach using one of two basal insulins, insulin glargine (Lantus) or insulin Detemir (Levemir), is now available, and many physicians initiate therapy with one of these insulins. The basal insulin is given once or twice daily in the morning, or at dinner, or at bedtime depending on patient and family wishes. The dose is adjusted up or down depending on the morning fasting glucose levels. The most physiologic insulin regimen is then to add H/NL prior to each meal and snack. Children who are unable to consistently receive H or NL at lunch or with snacks can receive H/NL with NPH at breakfast. The main advantage of Lantus or Levemir over two injections of NPH daily is that severe hypoglycemic episodes (particularly at night) are greatly reduced with their use.

2. Continuing insulin dosage—The total daily insulin dosage may need to be increased gradually to 1 U/kg (especially if ketones are present at onset). When gluconeogenesis and glycolysis are suppressed by insulin, a honeymoon or grace period is a common phenomenon. There is often a temporary decrease in the insulin dose during this period. This occurs 1–4 weeks after diagnosis in over 50% of children and tends to last longer in older children.

In helping families with day-to-day dosing of regular insulin or H or NL, some physicians initially use sliding scales, more recently referred to as “thinking” scales, to emphasize that the family must always be thinking about food recently eaten, or to be eaten, and recent or forthcoming exercise in addition to the blood glucose level. Examples of thinking scales are included in Understanding Diabetes (see references).

After the appropriate dosage of intermediate (eg, NPH) or long-acting (Lantus or Levemir) insulin is achieved, daily adjustments usually are not needed. However, small decreases may be made for heavy activity (eg, afternoon sports or overnight events). Many families gradually learn to make small (0.5–1 unit) weekly adjustments in insulin dosage based on home blood glucose testing. Understanding the onset, peak, and duration of insulin activity is essential (see Table 33–1).

As noted earlier, when one of the more physiologic (closer to human insulin output) basal insulins, Lantus or Levemir, is used, it must be given alone in the syringe or pen. When changing a patient from two injections per day of NPH insulin to Lantus or Levemir, the total 24-hour dose of NPH is divided in half to use as the initial dose. The dose of Lantus or Levemir is then increased or decreased 1 or 2 units every few days based on the fasting morning blood glucose levels. Common glucose level goals are 70–180 mg/dL (3.9–10 mmol/L) for preteens and 70–150 mg/dL (3.9–8.3 mmol/L) for teens. A rapid-acting insulin (H or NL) is then given before meals and snacks or a mixture of H or NL and NPH is given in the morning and H or NL at dinner. The dosages of H or NL may initially be based on a “thinking” scale (see previous discussion), and may later be based on carbohydrate-counting as the family becomes more knowledgeable (see discussion of diet, later).

Continuous subcutaneous insulin (insulin pump) therapy is being used more often in children, particularly for emotionally mature teens who are willing to do frequent blood glucose monitoring and to count carbohydrates. Basal insulin doses (usually H/NL) are chosen by the physician, with bolus doses prior to meals selected by the patient (or an appropriate adult) depending on the carbohydrate content of the food to be eaten. Insulin pump therapy is discussed in depth in Chapter 26 of Understanding Diabetes (see references).

---

*Available in various combinations to fit individual needs.

1. A mixture of 75% NPH and 25% Humalog.

2. NPH, neutral protamine Hagedorn insulin.
The following regimen constitutes intensive diabetes management: (1) three or more insulin injections per day, or insulin pump therapy; (2) four or more blood glucose determinations per day; (3) careful attention to dietary intake; and (4) frequent contact with the health care provider. This approach was shown in the Diabetes Control and Complications Trial (DCCT; see section on diet) to result in improved glucose control and to reduce the risk for retinal, renal, cardiovascular, and neurologic complications of diabetes. All teenagers with suboptimal glucose control who are willing to comply should be considered for intensive diabetes management.

3. Treatment of type 2 diabetes—The treatment of type 2 diabetes in children varies with the severity of the disease. If the glycosylated hemoglobin (HbA1c) fraction is still normal (or near normal) and ketone levels are not moderately or significantly increased, modification of lifestyle (preferably for the entire family) is the first line of therapy. This must include reducing caloric intake and increasing exercise. If the HbA1c fraction is mildly elevated (6.2–9.0%) and ketone levels are not moderately or significantly increased, an oral hypoglycemia agent can be tried. Metformin is usually tried along with modification of lifestyle, starting with a dose of 250–500 mg once daily. If needed, and if gastrointestinal adaptation has occurred, the dose can be gradually increased to 1 g twice daily. If the presentation is more severe, with moderately or significantly increased urine ketone levels, or blood β-hydroxybutyrate is more than 1.0 mmol/L, the initial treatment is reducing caloric intake and increasing exercise. If the HbA1c fraction is still normal (or near normal) and ketone levels are not moderately or significantly increased, an oral hypoglycemia agent can be tried. Metformin is usually tried along with modification of lifestyle, starting with a dose of 250–500 mg once daily. If needed, and if gastrointestinal adaptation has occurred, the dose can be gradually increased to 1 g twice daily. If the presentation is more severe, with moderately or significantly increased urine ketone levels, or blood β-hydroxybutyrate is more than 1.0 mmol/L, the initial treatment is similar to that of type 1 diabetes (including intravenous or subcutaneous insulin). Oral hypoglycemic agents may be tried at a later date, particularly if weight loss has been successful.

B. Diet

The mainstays of dietary treatment are discussed in detail in Understanding Diabetes (see references). The American Diabetes Association no longer recommends any one diabetic diet. Instead, nutrition therapy for diabetics should be individualized, with consideration given to the patient’s customary cultural eating habits and other lifestyle circumstances. Some families and children (particularly those with weight problems) find exchange diets helpful initially while they are learning food categories. Most centers now just use exchanges of carbohydrates, referred to below as carbohydrate-counting or “carb-counting.”

The DCCT found that four nutrition factors contributed to better glucose control (lower HbA1c levels): (1) adherence to a meal plan, (2) avoidance of extra snacks, (3) avoidance of overtreatment of low blood glucose levels (hypoglycemia), and (4) prompt treatment of high blood glucose levels. Two other nutritional factors include adjusting insulin levels for meals and maintaining a consistent schedule of nighttime snacks. The DCCT popularized the carb-counting dietary plan in which the dosage of H/NL or regular insulin is altered with each injection to adjust for the amount of carbohydrate to be eaten and the amount of exercise contemplated. One carbohydrate count is 15 g of glucose in the United States (10 g in the United Kingdom). A common formula is to use 1 unit of H/NL for each 15 g of carbohydrate eaten, although this ratio must be adjusted (using blood glucose levels 2 hours after meals) for each person.

C. Exercise

Regular aerobic exercise—at least 30 minutes a day—is important for children with diabetes. Exercise fosters a sense of well-being; helps increase insulin sensitivity; and helps maintain proper weight, blood pressure, and blood fat levels. Exercise may also help maintain normal peripheral circulation in later years. It is particularly important for children with type 2 diabetes.

Hypoglycemia during exercise or in the 2–12 hours after exercise (delayed hypoglycemia) can be prevented by careful monitoring of blood glucose before, during, and after exercise; sometimes by reducing the dosage of the insulin active at the time of (or after) the exercise; and by providing extra snacks. Children using insulin pumps should reduce preexercise bolus insulin dosages as well as the basal dosages during (and sometimes after) the exercise. In general, the longer and more vigorous the activity, the greater the reduction in insulin dose. Extra snacks should also be eaten. Fifteen grams of glucose usually covers about 30 minutes of exercise. The use of drinks containing 5–10% dextrose, such as Gatorade, during the period of exercise is often beneficial.

D. Stress Management

Management of stress is important on a short-term basis because stress hormones increase blood glucose levels. Chronic emotional upsets may lead to missed injections or other compliance problems. When this happens, counseling for the family and child becomes an important part of diabetes management.

E. Home Blood Glucose Measurements

All families must be able to monitor blood glucose levels three or four times daily—and more frequently in small infants and patients who have glucose control problems or intercurrent illnesses. Blood glucose levels can be monitored using any of the available meters, which generally have an accuracy of 90% or better. Target levels when no food has been eaten for 2 or more hours vary according to age (Table 33–2).

Blood glucose results should be recorded even if the meter has a memory feature. This allows the family to look for patterns and make changes in insulin dosage. If more than 50% of the values are above the desired range for age or more than 14% below the desired range, the insulin dosage usually needs to be adjusted. Some families are able to make these changes independently (particularly after the first year), whereas others need help from the health care provider. Children with diabetes should be evaluated by a clinician every 3 months. This provides an opportunity to
adjust insulin dosages according to changes in growth and blood glucose levels as well as to check for changes noted on physical examination (eg, eyes and thyroid). Continuous glucose monitoring (CGM) is now being used in some children and adolescents. Subcutaneous glucose levels are obtained every 1–5 minutes from a sensor placed under the skin. As with insulin pump therapy, additional education, usually at a specialty diabetes center, is required.

### F. Laboratory Evaluations

In addition to home measurements of blood glucose and blood or urine ketone levels, the HbA₁c level should be measured every 3 months. This test reflects the frequency of elevated blood glucose levels over the previous 3 months. Normal values vary among laboratories but are usually below 6.2% HbA₁c. The desired ranges are based on age. For the HbA₁c method, these ranges are as follows: 12–19 years, less than 7.5%; 6–11 years, less than 8.0%; and younger than 5 years, 7.5–8.5%. Higher levels are allowed in younger children to reduce the risk of hypoglycemia because their brains are still developing and they may not relate symptoms to hypoglycemia. Subcutaneous glucose levels are generally associated with a greater risk for hypoglycemia (see the following section). Using either method, longitudinal averages more than 33% above the upper limit of normal are associated with a higher risk for later renal and retinal complications. In the intensive treatment group of the DCCT, the lower HbA₁c values resulted in greater than 50% reductions in the retinal, renal, cardiovascular, and neurologic complications of diabetes.

Since atherosclerosis is the major cause of death in older patients with diabetes it is important to measure serum cholesterol, low-density lipoprotein cholesterol, and high-density lipoprotein cholesterol levels once yearly. Cholesterol levels should be below 200 mg/dL and low-density lipoprotein cholesterol levels below 100 mg/dL in postpubertal patients with diabetes.

When puberty is reached and the individual has had diabetes for 3 years or longer, the urinary excretion of albumin should be measured (as microalbumin) in two separate urine samples once yearly (see discussion of chronic complications, later). This can be done using timed overnight urine collections or first-morning voids (expressed per milligram of creatinine). Normal values differ with the methodology of the laboratory but are generally below 20 mcg/min (or 30 mcg/mg creatinine). People with type 2 diabetes should have this test done soon after diagnosis and then annually.

If the thyroid is enlarged (about 20% of patients with type 1 diabetes), the thyroid-stimulating hormone level should be measured yearly. This is usually the first test to become abnormal in the autoimmune thyroiditis commonly associated with type 1 diabetes.
